VOLUME 29 -- 1942

PUBLISHED BY THE SOCIETY MONTHLY
EXCEPT AUGUST AND SEPTEMBER

Publication Office: Free Press Printing Company, Burlington, Vermont
Subscription Price, \$8.00 per year

Entered as second-class matter at the post office at Burlington, Vt., May 4, 1939.

TABLE OF CONTENTS, VOLUME 29, 1942

No. 1, JANUARY

The development and distribution of the endodermis and an associated oxidase system in monocotyledonous plants.	D. S. VAN FLEET	1
Studies of South African Phaeophyceae. I. <i>Ecklonia maxima</i> , <i>Laminaria pallida</i> , <i>Macrocystis pyrifera</i>	GEORGE F. PAPPENFUSS	15
Parasitism among the chytrids.	JOHN S. KARLING	24
A cytological study of the carotene in the root of <i>Daucus carota</i> under various experimental treatments.	T. E. WEIER	35
Somatic chromosome complements in <i>Bouteloua</i>	JESS L. FULTS	45
Studies of the growth of pollen with respect to temperature, auxins, colchicine and vitamin B ₁	PAUL F. SMITH	56
Accumulation of nicotine in reciprocal grafts of tomato and tobacco	RAY F. DAWSON	66
Relation of seed weight to vegetative growth, differentiation and yield in plants	STANLEY W. OEXEMANN	72
Studies in the genus <i>Scirpus</i> L. IV. The section <i>Bolboschoenus</i> Palla	ALAN A. BEETLE	82
Water loss from excised leaves.	JOHN SHAFER, JR.	89
Some effects of photoperiod on leaf growth.	IRENE H. STUCKEY	92
✓ Factors controlling sporangial type in <i>Thraustotheca primoachlya</i> and <i>Dictyuchus achlyoides</i> . I.	S. B. SALVIN	97

No. 2, FEBRUARY

Freezable water content and the oxygen respiration in wheat and rye grain at different stages of ripening.	HAROLD G. SHIRK	105
The photodynamic action of neutral red on root tips of barley seedlings. Part II. Abnormalities of cells and tissue.	ELIZABETH KNIGHT PATTERSON	109
Inhibitory effects of inorganic compounds on photosynthesis in <i>Chlorella</i>	SYDNEY S. GREENFIELD	121
Stimulatory and toxic effects of copper sprays on powdery mildews	C. E. YARWOOD	132
Transport of thiamin in the tomato plant.	JAMES BONNER	136
Studies on <i>Chlorella vulgaris</i> . V. Some properties of the growth-inhibitor formed by <i>Chlorella</i> cells.	ROBERTSON PRATT	142
Some response of Valencia orange seedlings to varying concentrations of chloride and hydrogen ions.	H. E. HAYWARD AND WINIFRED M. BLAIR	148
Passage of air through plants and its relation to measurement of respiration and assimilation.	VIOLETTE F. C. GLASSTONE	156
Sexual hormones in <i>Achyla</i> . III. Hormone A and the initial male reaction	JOHN R. RAPER	159
Embryo culture an effective technique for shortening the breeding cycle of deciduous trees and increasing germination of hybrid seed.	W. E. LAMMERTS	166
A new species and variety of <i>Sclerocactus</i> from Arizona.	ELZADA U. CLOVER	172
A new fungus belonging to the Cladochytriaceae.	LELAND SHANOR	174

A developmental analysis of cell length as related to stem length	ELIZABETH BINDLOSS	179
Heredity susceptibility to x-ray injury in <i>Triticum monococcum</i> . .	LUTHER SMITH	189
Adventitious roots in stem cuttings of <i>Tropaeolum majus</i> L.	ARLO I. SMITH	192

No. 3, MARCH

A developmental analysis of inherited leaf patterns in <i>Tropaeolum</i>	W. G. WHALEY AND C. Y. WHALEY	195
On the nastic and traumatic responses in the pea test. . .	CHARLES L. SCHNEIDER	201
The influence of copper and iodine on the growth of <i>Azotobacter agile</i>	J. C. LEWIS	207
Surface relationships of roots and colloidal clay in plant nutrition	WM. A. ALBRECHT, E. R. GRAHAM AND H. R. SHEPARD	210
The influence of volcanic eruptions upon post-Pleistocene forest succession in central Oregon.	HENRY P. HANSEN	214
Metabolism of organic acids in excised barley roots as influenced by temperature, oxygen tension and salt concentration.	ALBERT ULRICH	220
Additional studies regarding the cation absorption mechanism of plants in soil.	R. OVERSTREET, T. C. BROYER, T. L. ISAACS AND C. C. DELWICHE	227
The significance of x-rays in studying the orientation of cellulose in the secondary wall of tracheids.	I. W. BAILEY AND EARL E. BERKLEY	231
Specificity of pyridoxine for excised tomato roots.	WILLIAM J. ROBBINS	241
Wood structure of the native Ontario species of <i>Juniperus</i>	M. W. BANNAN	245
The distribution and preparation of citrus peroxidase.	W. B. DAVIS	252
Some features of the structure of <i>Arctostaphylos viscida</i> . .	BERNICE E. DOYEL	254
A developmental study of three saprophytic chytrids. III. <i>Septochytrium variabile</i> Berdan.	HELEN BERENICE BERDAN	260
Distribution of structural hybrids in <i>Paeonia californica</i> . . .	JAMES L. WALTERS	270
The morphology of <i>Riella affinis</i> . II. Development of the sex organs, fertilization, and development of the sporophyte.	R. H. THOMPSON	275

No. 4, APRIL

Polyploidy in <i>Sedum ternatum</i> Michx. II. Cytogeography. .	J. T. BALDWIN, JR.	283
Alteration of potato starch grain structure under the influence of disease.	D. B. O. SAVILE	286
Structure of the apical meristem and development of the foliage leaves of <i>Cunninghamia lanceolata</i>	G. L. CROSS	288
The chromosomes and nucleoli of <i>Medeola virginiana</i>	ROBERT N. STEWART AND RONALD BAMFORD	301
Secondary spores in the mycelium of the cultivated mushroom, <i>Psalliota campestris</i> Fr.	ALBERT M. KLIGMAN	304
Inheritance of smut resistance in hybrids of Navarro oats	GEORGE M. REED	308
Carbon dioxide evolution during the induction period of photosynthesis	JAMES FRANCK	314
An analysis of the comparative rates of cell division in various parts of the developing cucurbit ovary.	EDMUND W. SINNOTT	317

Development and relative growth in ovaries of <i>Iris fulva</i> and <i>I. hexagona</i> var. <i>giganticaerulea</i>	HERBERT PARKES RILEY	323
Some recently collected specimens of <i>Schiedea</i> (<i>Caryophyllaceae</i>) and of Mexican Compositae.....	EARL EDWARD SHERFF	332

THE DEVELOPMENT AND DISTRIBUTION OF THE ENDODERMIS AND AN ASSOCIATED OXIDASE SYSTEM IN MONOCOTYLEDONOUS PLANTS¹

D. S. Van Fleet

IN THE course of a morphological and anatomical investigation of the plants in the genus *Smilax*, the author found that a detectable endodermis is generally present in subaerial stems and is absent in aerial stems (fig. 1, 3 and 4). A search through the literature failed to reveal a complete explanation for such an irregularity in the distribution of this tissue in endogenous plants, although Meyer (1881) observed the discontinuous endodermis of *Smilax*, and Schwendener (1883), Müller (1906) and others have recognized the effect of climate and habitat on this dermal layer in monocotyledons. Priestley and his students have described similar irregularities in the endodermis of dicotyledonous plants, and they have given a physiological interpretation to the problem and to the significance of the endodermis.

A preliminary examination of other liliaceous plants brought to light several instances of the same peculiar distribution of the endodermis throughout the stems. A few simple experiments have indicated that it is possible to induce the formation of this tissue in young aerial stems of monocotyledonous plants by introducing substratal factors around the growing stem. It is possible to modify the distribution and maturation of the endodermis by subjecting the growing stems to different types of soil, aeration, light, temperature, etc. Further experiments and observations on the roots and stems of plants in seventeen families of monocotyledons have established a series of basic relationships which may help to clear the way for future work on the development and function of the endodermis.

FACTORS INFLUENCING THE DEVELOPMENT OF THE ENDODERMIS IN ALLIUM ROOTS.—*Materials and methods.*—Since the general influence of environment on endodermal maturation is easier to study in roots, and particularly in roots which develop readily in water culture from bulbs, a series of experiments and observations on the roots of several varieties and species of *Allium* were conducted for the purpose of determining the conditions which influence the development of the endodermis.

The series of lamellae, which in most roots and stems give to the wall of the endodermal cell its characteristic appearance of centripetal development (fig. 2), may be taken as a key to maturational conditions, since these lamellae vary in thickness and in rate at which they are laid down and suberized. By

¹ Received for publication July 8, 1941.

The writer wishes to express his appreciation to Dr. Paul Weatherwax for suggesting a study of *Smilax* and for his help and advice in the ensuing investigation. He wishes also to thank Dr. Ralph E. Cleland for his helpful advice and criticism in the preparation of this paper. Acknowledgment is also due Dr. Walter F. Loehwing, Dr. Marion L. Lohman, and Dr. Ira T. Wilson for their suggestions.

sectioning a root at a point where the approximate age is known, it is thus possible to measure the development of the walls of the cells and, knowing their age, to plot their development against various causal and determinative factors. By taking the distance from the lumen of the cell to the middle lamella (fig. 5), it is possible to measure the development of the inner tangential wall in microns with a fair degree of accuracy and ease.

All sections were made free-hand and were taken from a region about one inch from the base of the bulb. By recording the day on which roots made their appearance it was thus possible to know the age of that portion of the root from which the sections were made. The sections were mounted in Scarlet R, Sudan III, Sudan IV, iodine, etc., but, for the most part, Scarlet R was used. No clearing agent was used, since any slight hydrolysis might swell the walls out of their normal configuration. For each causal factor studied, roots from at least three bulbs were used. Allowance was made for diseased or damaged roots, and only the oldest roots were used. Senescence and concurrent injury or disease were the only limiting factors to the duration of the experiments as far as the plants were concerned.

Experiments were designed so as to make possible a study of the rate of centripetal deposition in endodermal walls when influenced by one or more of the following environmental factors: aerated and non-aerated solutions, aerated and non-aerated soils, chemical nutrients, tannic extracts, light, temperature and hydrion concentration. Where water media were used, the bulbs were placed on galvanized wire screens coated with Valspar, and the containers on which the screens rested were either glass battery jars or a similar type of jar or a galvanized tank painted with Valspar. The water was maintained at a constant level by a controlled reservoir supply coming in at a rate slightly greater than the evaporation from the container. A fixed outlet that did not allow the level of the water to drop prevented the base of the roots from being exposed to the air. Where it was desired, the position of the outlets or the screens was changed so that there was a constant exposure of a portion of the roots to the air. A fluctuating water level was obtained by using an automatic siphon, the details of which are too lengthy to present here. Where aeration was needed for a medium, it was accomplished by means of an electric aerator or several devices of a type described by Weatherwax (1915), which bubbled air through the solution. Hydrion concentration was determined colorimetrically, and it was not necessary to modify this factor, since there was for most media, unless otherwise desired, a range of pH 6.2–7.2.

Fig. 1-4. Endodermis of *Smilax* stem.—Fig. 1. Diagram to show cylinder endodermis in internodes below ground with sporadic or bundle endodermis in the region of the ground line and the absence of endodermis in the aerial stem.—

TABLE 1. The influence of the external medium on the centripetal development of endodermal walls in *Allium* roots. Growth period 35 days. Each + sign represents one micron of deposition. Where there was no thickening the reading appears as a dash (—). The symbol —1 is used when the thickening was less than one micron.

Each type of *Allium* studied was subjected to a series of individual experiments which imposed a distinct influence or set of influences on the endodermis. The results of these individual experiments are presented in graphic form in tables 1, 2 and 3. The individual experiment is given a number and the conditions of the experiment are listed in the first column, thus making it easy to compare the effect of the various environments on the endodermis of a

given species or variety, and at the same time making possible a comparison between varieties.

The development of the endodermis in roots of *Allium sativum*.—As indicated in table 1, the conditions which serve to give the quickest maturation and suberization of the endodermis result from a constant fluctuation of moisture conditions and aeration. If the roots are alternately bathed with well aerated water and exposed in such a way that they become

TABLE 2. Experiments on *A. Ceba* (Yellow Danver). Nutrient solutions in both aerated and non-aerated water-cultures were used for a growth period of twenty days. Where centripetal development was less than one micron the reading is —1.

<i>A. sphaerocephalum</i>	Sandy loam	160 days	6 microns

dry but not desiccated, an endodermis will develop (table 1, experiment 1) which is quite in contrast with that attained by growing under conditions of poor aeration (table 1, experiment 7). This treatment, however, will not induce as elaborate a development of endodermis as will subjection to a fluctuating water level in sand (compare experiments 2 and 10 in table 1).

Perhaps the most conclusive evidence derived from the work on *A. sativum* is that obtained from aerotropic roots (fig. 5, and experiment 3 and 5 in table 1). The portion of the root above the ground develops a greater centripetal thickening in the endodermis than that below ground. It may be inferred from the evidence that the amount of gas which goes into the cortex, as well as incipient desiccation, acts as a stimulus to the centripetal thickening of the walls.

A fluctuating water and gaseous supply evidently far overshadows any other set of external environmental conditions, such as salts, light, etc., in its effect on endodermal maturation in *A. sativum* roots. The extreme reverse of these conditions would be where the roots are subjected to a decreased or detrimental gaseous supply as, for example, in a carbonic acid gas medium (experiment 15, table 1). The un-aerated tannic extract medium (experiment 11, table 1) quite evidently has an inhibitory effect which will be explained later, and which will assume considerable significance in the light of evidence which will be presented on an oxidase system which the author has found to be associated with endodermal wall formation.

The development of the endodermis in roots of Allium Cepa (White Globe).—Like *Allium sativum*, *Allium Cepa*, of the White Globe variety, also shows the greatest centripetal development of endodermal walls when subjected to a fluctuating water level (experiment 1, table 1), whereas constant exposures of the roots to air and to aerated and non-aerated water media do not produce any remarkable differences in their effect on the elaboration of the endodermis. The behavior of endodermal cells in a calcium nitrate solution (experiment 13, table 1) is one of hurried

maturation, and it diverges from the usual slow ex-centric development. This was also true in *Allium sativum*.

Similar experiments were conducted on other varieties of *A. Cepa* (Red Wethersfield, White Seed, and Yellow Danver) with almost identical results. The endodermis of White Seed Onions responds to a fluctuating water level just as does the Mature White Onion (White Globe). The young bulbs and old bulbs both produce roots whose endodermal cells mature at about the same rate in the same media. It should be pointed out at this time that the removal of the outer scales from a bulb results in a more pronounced development of endodermal walls of the root. This was also true in White Globe bulbs which had been sectioned transversely into two halves, the injured bulb producing roots with a more pronounced endodermal development than is found in roots from normal bulbs. The mature bulbs of the Red Wethersfield type respond readily to exposure to air and to a fluctuating water level. The seed onions of this variety are slow in the maturation of their endodermal cells in ordinary aerated tap water, as are also the seed onions of the White Globe type. When roots of the Red Wethersfield are exposed to air, the maturational rate is increased. Again aeration and exposure of the roots are conducive to endodermal maturation in Yellow Danver onions. It is of interest to note that the Casparian strip develops in experiment 15 (carbon dioxide) as it always does in this variety, regardless of the type of aeration. This would lead one to believe that the Casparian strip represents an anaerobic phase in the development of the endodermis, or that there is a cortical oxygen supply from the bulbs. This was also found to be true in *A. sativum*.

A study of the various nutrients as they influence the development of the endodermis in *A. Cepa* (Yellow Danver) in both aerated and non-aerated solutions (table 2) indicates that solutions low in nitrogen are conducive to heavier deposition of ligneous and suberous materials. Solutions high in nitrogen do not bring about centripetal deposition, but solutions high in calcium do give a more marked deposition.

In general the concentration of any one salt does not have as great an influence on the development of the endodermis as does the extent of aeration. Experiments being conducted at present indicate that a fluctuation in concentration has about the same influence as a fluctuation in water and gas supply.

The development of the endodermis in roots of Allium Cepa var. solanicum.—As in the aerotropic roots of *A. sativum*, the portions of roots of *A. Cepa* var. *solanicum* grown above the substratum show a more rapid centripetal thickening of the endodermal walls than those portions grown below (experiments 3 and 5, table 1). A slightly fluctuating water supply in a loam medium (experiment 12, table 1) has a more pronounced influence on the rate of suberogenic substances than does the fluctuation of the water level in water culture. There is no difference between aerated and non-aerated tap water or distilled water so far as the early development of the endodermis is concerned (experiments 7, 8 and 12, table 1), and apparently light or the absence of light does not incite any difference in the development of the endodermis in the same medium (experiments 7, 8, 9 and 10). Aerated and non-aerated tap water, whether in the light or dark, has the same, or about the same, influence as aerated or non-aerated distilled water in the light or the dark.

The influence of tannic extracts on the development of the endodermis in the roots of three types of onions.—Tannin apparently acts as a retarding factor in the unilateral differentiation of endodermal walls. Its action is to take out of solution the available dissolved oxygen. This is evidenced by the "browning" of the solution as a result of oxidation. It is further possible that it may act as an anti-oxidant; this is a point which is further suggested by observations on oxidase activity. In the three types of *Allium* subjected to this medium it is quite evident that tannins do not alter the trend of response. The difference in development between *A. sativum* and *A. Cepa* var. *solanicum* in tannic extract is typical of the difference between these two types in several media, and it is further true that *A. Cepa* var. *solanicum* shows the least centripetal development of all forms studied regardless of the medium of growth. From these preliminary observations and conclusions, it becomes evident that the apparently fundamental difference between the various types of onions in respect to response of endodermal tissues is perhaps in part due to the presence of inhibitive tannins. These tannins are present most prominently in the scale leaves of *A. Cepa* var. *solanicum*, and it is this species which shows the maximum effect of some inhibitive or retarding force. The tannins may occasionally be found in the bases of the roots, and they have in a few cases been found to occupy a place in the developing tangential walls of the endodermal cells. *A. sativum*, of the variety used, is notably free of tannins in both bulb and root. The White Globe, Yellow Danver and Red Wethersfield varieties apparently occupy an intermediate position both in re-

sponse to media and in quantity of tannins present in their tissues.

The difference between surface and substratal portions of the same roots (aerotropic) in two types of onions.—As was stated earlier in connection with aerotropic roots of *Allium sativum* (see fig. 1) the aerial portions of the roots show at least twice as great a centripetal thickening as do the walls of even older cells from the subaerial portions. The response of the three types of onions is again indicative of an inherent pattern which is difficult if not impossible to break or alter. Again the three types remain distinct in their expression, but *A. Cepa* var. *solanicum* shows the least tendency to respond. As subsequent data may show, there may be a passage of inhibitory substances from a portion of an organ in one medium to a portion in another medium. This is particularly true where injury to the bulb results in a greater development of the endodermis in roots on the injured bulb.

A comparison of three types of onions in their response to a fluctuating water level.—This medium represents the optimum condition for centripetal expression in the endodermis of *A. sativum* and *A. Cepa* (White Onions); however, *A. Cepa* var. *solanicum* is characterized by a greater centripetal thickening of endodermal walls in a sand medium with a fluctuating water level, or in a fluctuating water level in sawdust. The author believes that *A. Cepa* var. *solanicum* develops a more definite cuticular barrier than the other two forms. Sand and sawdust media for some reason apparently retard the formation of a functional cuticle. In a portion of a root freely exposed to moist or dry air and under light conditions favorable to cuticular deposition, there is a possibility of an interrelationship between cuticle formation and the development of the endodermis. This relationship is more strikingly shown in stems than in roots.

Conclusions based on experimental evidence obtained by varying the environmental growing conditions for Allium roots.—Obviously there is an inherent physiological pattern that may be modified; and, even for any one variety, the pattern remains rather fixed. There is no one factor more significant than another in determining the maturational rate. Some general statements can be made, however, as to the effects of certain sets of factors or basic environmental relationships that influence the rate of maturation. These relationships, as summarized from the tables, may be stated briefly as conclusions.

Neither constant dryness nor constant moisture, especially under conditions of poor aeration, are conducive to endodermal maturation. A fluctuation of dry-moist conditions, accompanied by constant aeration, is apparently most conducive to deposition. Various nutrients apparently do not greatly modify the rate of deposition. The absence of dissolved oxygen in a solution or very moist medium tends to retard greatly the deposition of suberic substances. The accumulation of carbonic acid gas in the medium, or its artificial introduction, allows the formation of the

Casparian strip alone and retards suberic deposition. In some cases tannic substances are almost as effective as carbonic acid in retarding suberic deposition. The section on oxidases will make clear the exact relationship of tannins to endodermal maturation. The presence or absence of light apparently does not have any effect except as it probably modifies the amount of gaseous and dissolved oxygen in the medium and tissues of the plant. A condition of incipient desiccation and plasmolysis resulting from external environmental factors is recognized as a possible explanation for centripetal development of endodermal walls.

Discussion.—The author, in attempting to clarify the formational factors in the development of the endodermis, has gone back to Schwendener's (1883) premise that, "Hieraus erklären sich zugleich die Beziehungen zu Klima und Standort . . . die Wurzeln der Felsen- und Steppenpflanzen verstärkt Scheiden besitzen. . . . Wo dagegen der Standort constant weich und feucht bleibt . . . da sind die Scheiden der Wurzeln ohne mechanische Verstärkungen. . . ." This statement has been taken as a basis upon which to start this investigation.

The necessity of oxygen for the formation of cuticular and suberic substances, found in dermal barriers, was first noted by Kny (1889). He demonstrated that the exclusion of oxygen from the cut surface of a potato will prevent the formation of wound periderm. Priestley and Woffenden (1922), in studying the causal factors in cork formation, have confirmed the results of Kny and other workers on the necessity of oxygen for suberization. Priestley and North (1922) concluded that the mature endodermal walls are made up of condensation products of suberogenic or fatty acids not found in cork. Later Priestley and Rhodes (1926) made a macrochemical study of the endodermis and found suberin-like materials, similar to those in potato cork, present in endodermal cells in the tertiary or mature stage. They pointed out that it is probable that suberin lamellae arise from fatty substances as a result of oxidation and drying and stated further, "It has been demonstrated that the occurrence of these complexes depends on the air supply." Priestley (1921) had earlier stated that suberin may be regarded as "an aggregate of variously modified forms (condensation products or anhydrides)." Thus it is that earlier workers came to associate oxygen or desiccation with suberic deposition; and, more recently, Bloch (1935, 1937), in studying wound healing in *Tradescantia* and in roots of *Phoenix reclinata*, has shown that suberization and formation of wound gum are dependent upon an adequate oxygen and sap supply.

It should not be supposed that increased oxygen supply in the medium will bring a response in suberin-depositing tissues alone. There is a danger in assuming that suberin is the only substance deposited in endodermal and wound tissues. Loehwing (1934) has pointed out that there is an increase in size of organs and nutrient absorption and an increase in

wall thickening of all cells in roots of continuously aerated plants. Bryant (1934) also has found the thickness of the walls of all cells of barley roots to be twice as great in aerated as in non-aerated solutions. Oxygen and adequate aeration are necessary for all types of deposition, and this must be taken into account in any study of suberic and related depositions. Hence, it is quite possible that dissolved oxygen has some effect on the ultimate sources of suberin rather than on the actual mechanism of deposition.

Priestley (1924), and Priestley and Lee (1924) have presented evidence that the calcium in the substratum is responsible for the immobility and deposition of suberin in roots so that there is less deposition in stems. They further believe that potassium acts to bring the soluble condition and free mobility of these same fatty acids up into the stems. Hence suberization and cuticularization are thought to be increased in stems but not in roots by an increase in potassium or a decrease in calcium in the soil.

The author has found suberization to be prominent in the endodermis of the mesocotyl of corn plants grown in solutions of calcium nitrate. Plants of the same age grown in a potassium nitrate solution show only a weak Casparian deposit, and the cells are in some cases about 30 per cent larger in a radial direction and in total volume. The endodermal cells opposite the xylem in normal roots are often radially enlarged and are more rounded than those opposite the phloem; this condition is, I believe, indicative of a difference in osmotic relationships between tissues, and the nitrate solutions apparently disturb these normal relationships.

Millner (1934) has made an ecological anatomical study of *Silene vulgaris* in which he finds that the conditions of the soil have a bearing on suberization. He finds that clay-grown plants show the least periderm and only a slight suberization, whereas sand-grown plants show a copious suberization, and other soils are intermediate in their effect. This conclusion is, in general, a valid one for suberization and endodermal maturation in *Allium* according to the results I have obtained, and it restates very clearly the observations and inferences originally made by Schwendener (1883).

*AN OXIDASE SYSTEM ASSOCIATED WITH THE ENDO-
DERMIS.*—The exact mechanism of suberization in dermal layers has never been fully understood. Drabble and Nierenstein (1906) were perhaps the first to suggest and demonstrate that suberin is formed from the condensation of tannins and fats. Priestley and his students also believe suberization to be a condensation reaction and that the oxidation or condensation of unsaturated fatty acids takes place wherever suberin lamellae are being formed. However, oxygen and the necessary suberic substances may often be present, and suberin lamellae will still not form unless, for example, the tissue is wounded or becomes dry. Desiccation alone is not a primary causal factor in suberic condensation, since the relative humidity must be fairly high for most

suberization, and it is also apparent that a definite excess or minimum of oxygen is not essential. This would suggest that there is perhaps a more complete mechanism than has heretofore been proposed.

Tunmann has stated (1913, p. 427) that tannins are changed to phlobaphenes by oxidases. Priestley and North (1922) found tannins of the phlobaphene group associated with the endodermis of *Pteridium aquilinum*, and the author has found phlobaphenes in the monocot endodermis. Grüss (1910), Tunmann (1913), and others have pointed out the existence of oxidases in wounded tissues, although there is nothing in the literature on their causal relation to cicatrization and suberization. Samish (1935) has found oxidases in apricot fruits located around, but not in, stelar tissue. Sanglet (1928) has found oxidases localized for the most part in the bundle sheaths of *Ilex* leaves.

The author has made a few preliminary observations and has found an oxidase system associated with endodermal tissues and mestome or bundle sheath tissue in many monocotyledonous plants. It is not intended that the material presented here be taken as proof of a causal relationship between oxidases and endodermal maturation; it is my belief, however, and it will be plain in the discussion which follows, that the presence of an oxidase system in endodermal tissues may be a causal factor in endodermal and related suberic depositions. As a result of this study certain other observations have been made on the effect of the mature endodermis on oxidase distribution, and it is believed they indicate a further relationship between the function of the endodermis and the ultimate development of other tissues around it.

The endodermal oxidase system.—Solutions of various oxidase indicators were used to determine colorimetrically the presence and location of oxidases in, and associated with, the developing and mature endodermis. Many of the reagents and methods used by Onslow (1920, 1921, 1931) and Joyet-Lavergne (1935, 1937) and outlined by Boswell and Whiting (1940) were employed to determine the presence of both oxidases and reductases. Solutions of aloin, aesculin, vanillin, alpha-Naphthol, paraphenylenediamine, "Nadi" reagent, meta-phenylenediamine, benzidine, diphenylamine, diphenylbenzidine, guaiacol, and various oxidation-reduction indicators were used for the detection of oxidases in living sections of roots and stems. For much of the work guaiacol and "Nadi" reagent were used in the direct reaction for the detection of organic peroxides and peroxidases. Hydrogen peroxide was not used very often with guaiacol in the indirect guaiacol reaction, since in most cases the direct reaction indicated the presence of organic peroxides located in the walls and intercellular spaces of endodermal cells, and peroxidases were almost always present. Sodium cyanide, hydrogen sulphide, boiling water or alcohol either inactivate, remove, or precipitate the organic peroxides, but they are apparently not removed as readily as the peroxidases. Cold alcohol does not remove the oxi-

dase system. Oxidized guaiacol, benzidine, and "Nadi" reagent are only weakly absorbed in endodermal cells or walls. Hence the localization of colorimetric reactions is not entirely an adsorption phenomenon.

There are oxidases in the developing Casparian strips of *Allium* roots (fig. 6) and also in the intercellular spaces. Similarly the underground stems of

Fig. 5. Arabic numerals 1 and 2 indicate two distinct portions in the same root, the above ground aerotropic portion (1) and the below ground portion (2). The condition of the endodermis in these two regions is indicated by the diagrams numbered 1 and 2 to indicate the portion of the root from which they were taken.

Smilax glauca (fig. 8) and *Smilax ecirrhata* have an oxidase system located in the developing Casparian strip, the plasma membrane, and the intercellular spaces. The inner tangential walls of the endodermal cells of *Smilax ecirrhata* show an oxidase system associated with suberic deposition. These walls are the first to show a suberin lamella. The centripetally developing endodermal cells of *Maianthemum* stems (fig. 7) have oxidases in the portions of the wall which are youngest, next to the lumen, before the deposition of tannic substances which apparently inhibit the oxidases. The quantity of tannin present in younger lamellae is not sufficient to mask the colorimetric determination. *Maianthemum* roots like those of *Allium* have oxidases in the developing Casparian strip (fig. 9) and also in the inner tangential walls, which at the same time or a little later have suberic lamellae deposited on them.

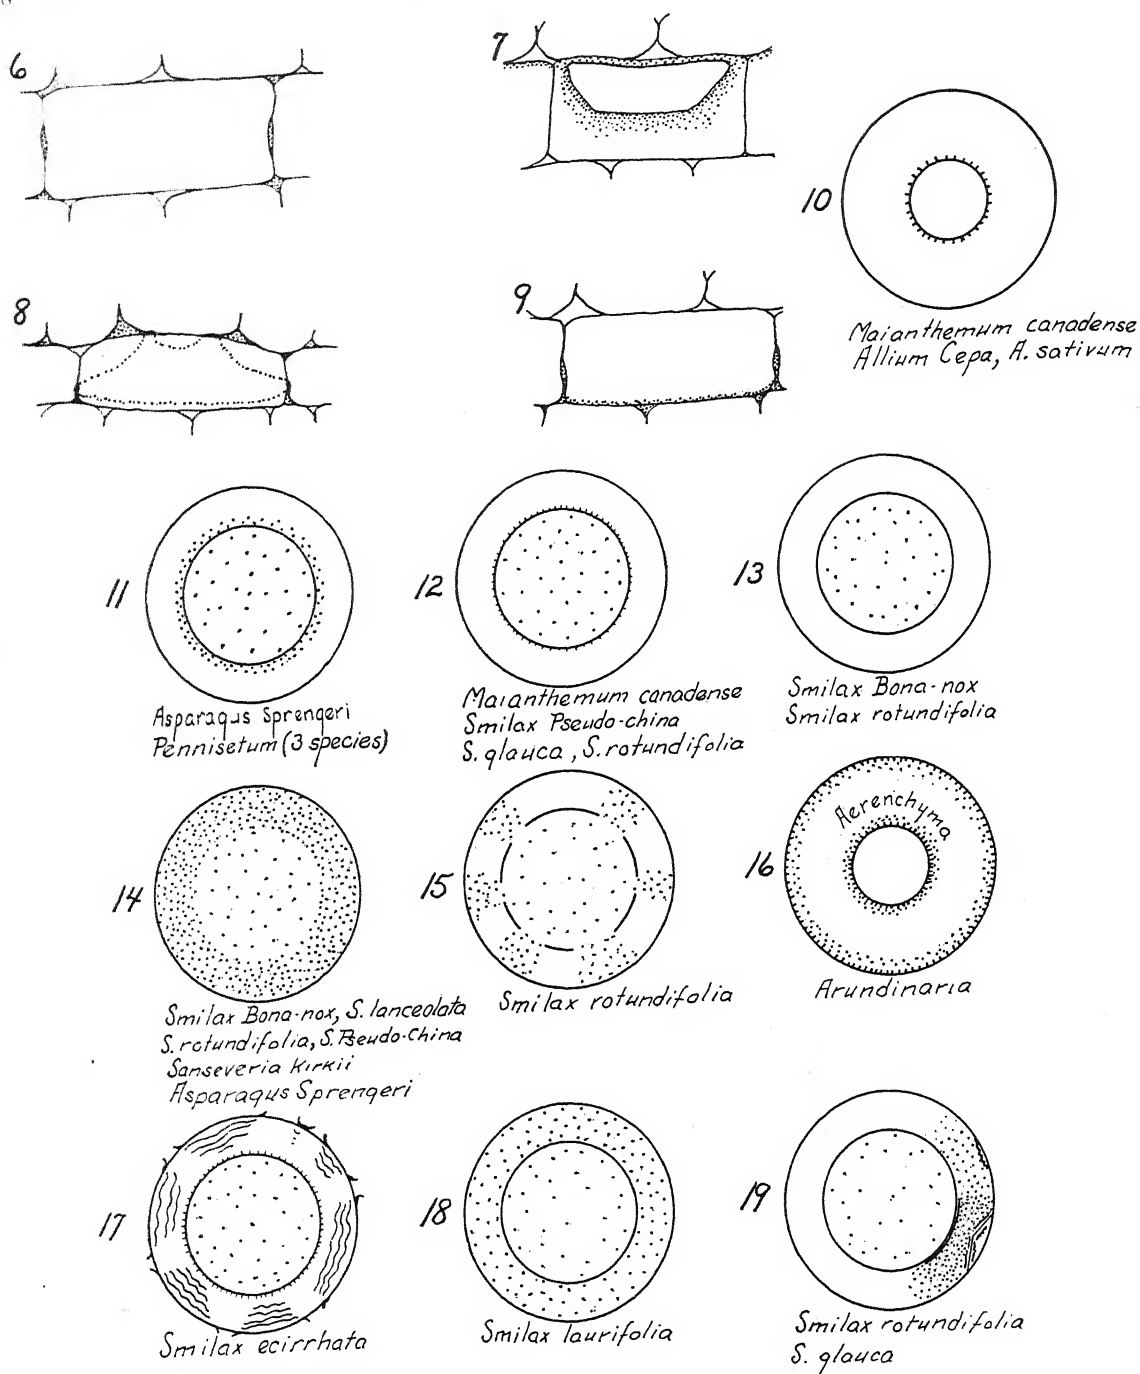

Fig. 6-19. Stippling indicates extent and relative quantity of oxidase activity.—Fig. 6-9. Oxidases associated with development of endodermal deposits.—Fig. 6. Endodermal cell of *Allium* root showing Casparian strip.—Fig. 7. Centripetal deposition in endodermis of *Maianthemum* stem with greatest oxidase activity in younger lamellae next to lumen.—Fig. 8. Endodermal cell with Casparian strip deposits near four intercellular spaces in stem of *Smilax glauca*.—Fig. 9. Endodermal cell from *Maianthemum* root.—Fig. 10-19. Diagrams of stem and root transverse sections to show distribution of oxidases and endodermis.—Fig. 10. Diagram of root to show complete cylinder endodermis and oxidases more prevalent inside endodermis than in cortex.—Fig. 11. Stem, complete endodermis and more or less confined oxidases.—Fig. 12. Stem, cylinder endodermis and confined oxidases.—Fig. 13. Same.—Fig. 14. Absence of endodermis in aerial stem and oxidases not confined to stele.—Fig. 15. Oxidases in cortex where gaps occur in endodermis in stem in region of ground line.—Fig. 16. Root, oxidases associated with hypodermis and endodermis.—Fig. 17. Decorticated stem and confined oxidase system.—Fig. 18. Poorly developed endodermis in subaerial stem and oxidase system

Oxidase activity is greater in those endodermal cells opposite the phloem, and this, of course, is related to the fact that endodermal cells show the greatest centripetal thickening in this region. The cells opposite the xylem have Casparian strips and associated oxidase activity in these same radial walls and strips; however, oxidases are not as prevalent in the tangential walls of endodermal cells opposite the xylem, and these walls often remain unsuberized throughout the life of the tissue. This was observed in the roots of *Aloe*, *Dracaena*, *Smilax*, *Allium* and numerous other forms. Likewise the suberic centripetal development of the mestome sheath is most prominent opposite the phloem portion of the bundle, and it is in this region that oxidase precursors are apparently most prevalent. Colorimetric determinations show oxidases in the phloem and across the intervening sclericycle between phloem and endodermis with the most intense reaction in the endodermis and the phloem. We have, therefore, concluded from these and other observations that the oxidase system has its origin in phloem, in part, and that it becomes functional along with suberic precursors at the endodermal barrier.

The absence of the endodermis in aerial stems of monocotyledonous plants may be due to the absence of a complete oxidase system at the locus of the endodermis. Preliminary tests indicate that catechol tannins are more prevalent in young underground stems than they are in young aerial stems. The oxygenase which catalyzes the production of a peroxide from these catechols may be inactivated by light. At least one or both of these two essentials to organic peroxide formation are not present in detectable quantities at the peripheral edge of the sclericycle in aerial stems but are found in small amounts throughout the cortex. This may have some bearing on the absence of the endodermis in aerial stems. At the same time there is the relationship to cuticle formation of the endodermis. I have found that the cuticle is from 10 per cent to 75 per cent thicker above the surface of the soil than it is below, and Priestley and Lee (1924) have found this to be true of dicotyledonous plants. Coupled with this I have observed that in aerial stems the oxidases apparently do not halt at the histogenic endodermal zone, but move on out to hypodermis and epidermis. Hence, it is conceivable that the cuticle is functional at an early stage and prevents the inward disturbance of normal oxygen gradients so that an excess of oxygen or a condition of incipient desiccation and plasmolysis is prevented. The oxidase system would thus not meet an oxygen supply adequate for the formation of organic peroxides in quantities sufficient to release active oxygen to aid in suberic deposition. It is interesting to note the prevalence in many young *Smilax* stems of anthocyanins in the peripheral regions of the cortex at the ground-line. This suggests an oxidase system and an oxygen-holding system which might act to prevent the inward movement of oxygen at a time when

the cuticle is not fully developed. The endodermis does not form in this region at all. There are some further observations listed below which may clarify this very interesting and complex relationship.

In *Pennisetum longistylum*, *P. Ruppelianum*, and *P. japonicum* the direct reaction with guaiacol shows the greatest oxidase activity in underground stems and rhizomes, in the zone of the endodermis. The oxidases are not confined to this region in the aerial stem but are found throughout the cortex. *Asparagus Sprengeri* (fig. 11) also has a confined oxidase system in portions of the stem below the surface. In some cases the oxidases are located only in the outer tangential walls of endodermal cells. In aerial stems the oxidase system is not confined but is spread throughout the cortex.

In *Maianthemum canadense* (fig. 12) oxidases are present within the endodermal walls in the rhizome of young developing tissues, but in November, when the plant is dormant and after tannins have accumulated, the oxidases are apparently inhibited or their precursors are not present. Similarly in underground stems of *Smilax glauca* (fig. 12) the oxidases are in the intercellular spaces and the outer tangential walls, and are masked by the tannins in the inner tangential walls, although it is true that even at younger stages, before tannins can be detected (by ammonia vapors, oxidizing agents), the oxidases are largely confined to the outer tangential walls. Both aerial and underground portions of etiolated *Smilax glauca* stems show the same confinement of the oxidase system as indicated by the direct reaction with guaiacol. *Smilax rotundifolia* (fig. 12) has its oxidase system confined where there are conditions which lead to endodermal formation, but in aerial stems (fig. 14) the system is spread throughout the cortex. This is also true of the distribution of oxidases in the stems of *Smilax Bona-nox*.

Decorticating stems of *Smilax ecirrhata* (fig. 17) have a highly active oxidase system which is most intense within the tangential walls of the endodermis. The inner tangential walls and the radial walls of endodermal cells in decorticated plants of *Smilax ecirrhata* and *Smilax herbacea* show particularly well the presence of oxidases.

The endodermis of *Smilax laurifolia* (fig. 18) is not always well defined in underground portions of the stem, and it is often not unilaterally thickened, whereas most *Smilax* endodermal cells are very thick-walled (fig. 2). The endodermis in this species does not always form a complete cylinder; and, even when it does, it is only possible to identify it by using hydrolytic reagents on the sections. The oxidase system is not confined but is present throughout the cortex.

Natural or artificial wounding of the cortex of *Smilax rotundifolia* and *S. glauca* (fig. 19) results in an oxidase system which is largely confined to the zone of the wound and is more intense just outside and in the endodermis than it is in the endodermis of

not confined.—Fig. 19. Wounded stem with greatest oxidase activity in region of wound and greater deposition in endodermis in this region.

normal unwounded tissue. The endodermis at this point is much more strongly developed than in other portions of the same stem.

Portions of mature underground stems of *Smilax Bona-nox* (fig. 14) which lack an endodermis show a natural oxidation and browning of the entire cross-section, and oxidase indicators show the same results. Water extracts of cortical tissue, from stems which lack an endodermis, give a faint blue color by the direct guaiacol reaction and a deeper blue color on the addition of hydrogen peroxide. Cortical extracts from mature stems with an endodermis (fig. 13) do not give either the direct or the indirect reaction with guaiacol.

Dormant stems of *Smilax rotundifolia* (fig. 14), either aerial or substratal stems, which lack an endodermis, will show natural browning of the entire fresh section within about five minutes. Likewise oxidase tests by the direct reaction show a complete oxidase system throughout the cortex. Where the endodermis is discontinuous (fig. 15), the oxidase system in the cortex is confined to those portions of the cortex where there are gaps in the endodermis. It must be pointed out here that the cuticle is sometimes fifteen microns thick in substratal stems of *Smilax rotundifolia* which lack an endodermis, whereas it is less than eight microns thick in stems which possess an endodermis. A thick functional cuticle may prevent the inward sweep of excessive amounts of gas so that the oxidase system perhaps does not become complete at the endodermal histogen. This histogen is really just the boundary between two distinct physiologic systems, the cortex and the stele or the cortex and the sclericycle, and it is, I believe, logical to suppose that effusa from one system may become halted or deposited at the boundary of another. Horizontal underground stems of *Smilax rotundifolia*, which run along in a layer of clay covered by humus, often lack an endodermis but have a thick cuticle. If one of these stems is cut off, or if the terminal bud is killed, the branches which develop from other buds back of the tip will possess an endodermis regardless of whether they continue as prostrate stems or whether they grow vertically upward through the humus layer to become aerial stems. The cuticle of these stems is appreciably thinner, and the oxidase system is confined, whereas in the main stem it was complete in its distribution. Back of the cut surface of the parent stem there is an accumulation of organic peroxides and tannins. There is undoubtedly a causal connection between the accumulation of these substances and the development of the endodermis. The author is conducting an experiment which may give some additional and more conclusive evidence.

Certain *Arundinaria* roots (fig. 16) are peculiar in that they have a centripetally thickened hypodermis whose inner tangential walls are thinnest, so that they are the mirror images of the endodermal cells whose outer tangential walls are thinnest. Between these two dermal layers there is a large aerenchymal cavity or series of cavities. The oxidase system is

confined to the hypodermal and endodermal layers and to the intercellular spaces immediately adjoining these dermal barriers.

Discussion of endodermal oxidase system.—Oxidases in the endodermis have not hitherto been recorded, but their presence in related tissues, the bundle sheaths, have been pointed out by Keeble and Armstrong (1912), Sanglet (1928), and Samisch (1935). The significance of oxidases to the maturation and function of any one tissue has not been made clear, although there are many papers which deal with the distribution of oxidases and the difference in the oxidation and oxidation potential in the organs of the same plant.

Raciborski (1898a and 1898b) was one of the first to point out oxidases in the phloem. As I have pointed out, endodermal development and oxidase activity are both more pronounced opposite phloem than opposite xylem. Oxidases may be traced by indicators from the phloem out to the endodermis, and that oxidative activity is greater in this region is evidenced by natural browning of the tissue. It is possible that the oxidase system moves out from the phloem in all directions, but the conditions are most favorable for its expression in the endodermis, sclericycle, or cortex. If oxidases move in toward the center of the stele, they are inhibited or are in some manner incomplete. All of the examinations that I have made lead me to the conclusion that the oxidase system in the endodermis has its immediate origin in the phloem, and the greatest centripetal development is opposite the phloem. Scott (1928) and others have observed that the Casparian strip does not appear before phloem elements are differentiated.

The intense oxidation of aromatic substances to give a definite browning of the tissues outside the phloem is accomplished only where a definite endodermal barrier has been formed. The endodermis tends to hold the constituents of the oxidase system so that they are accumulated and destroyed or held in abeyance. The inhibition of the system is dependent upon the presence of dissolved oxygen and the release of active oxygen from the organic peroxides of the system. The accumulation of oxidized aromatics, or in other words the accumulation of tannins, tends to inhibit the oxidase system. As a result, at the endodermis there is a constant fluctuation between the oxidation and deposition of tannic and suberic substances, and the inhibition of the oxidase system. It follows, therefore, that oxidation is not complete, and this is indeed true as demonstrated by the unsaturated nature of the suberic substances in the cellulose matrix (as indicated by iodine, osmic and Sudan stains).

If the fatty acid precursors to suberization were completely oxidized there would be no deposition. Deposition may include an oxidase system and accumulated tannic substances acting against each other so as to bring about incomplete oxidation and centripetal deposition. This fluctuating system, responsible for fatty acid deposition, may be the thing that is influenced by environmental factors, and there

may be no direct environmental influence on fatty acid deposition itself.

The observations presented here on the confinement of the oxidases to a given region in substratal organs and the associated presence of an endodermis may not be too clearly established as a causal relationship in the maturation of the endodermis, but there are some other observations which are indicative of conditions which have their influence on maturation in terms of an enzymatic system. For example, it is possible that calcium nitrate solutions do not influence suberization directly, as postulated by Priestley and his students, but rather that such solutions affect oxidase activity. Oxidase activity is higher in onion bulbs of the anthocyanic type than in those of the albino variety as pointed out by Wheldale (1916) in reviewing Katic's work. Thus in the bulbs of *Allium Cepa* var. *solanicum* the oxidase activity is higher than in the bulbs of *Allium sativum* and *Allium Cepa* of the White Globe variety as evidenced by the presence of anthocyanins in the former and their absence in the latter. Anthocyanin is an oxygen acceptor, and it may be argued that the high oxidizing properties of anthocyanic tissue might affect the formation of organic peroxides which find their way to the roots or the amount of dissolved oxygen which enters the roots from the bulbs.

Summary of endodermal oxidase system.—An oxidase system is associated with endodermal maturation, and it may be causally related to the location and ultimate formation and function of the mature endodermis. The following statements may be made as to the possible relationship of oxidases and related factors to the formation of the endodermis.

When the cuticular barrier is poorly developed, the increase in the gaseous content and incipient desiccation in the cortex brings about the confinement of the oxidase system to the locus of the ultimate endodermis. The oxidase system is not confined when the cuticle is well developed. The oxidase system helps to bring about, by means of active oxygen, the oxidation of fatty acids and certain aromatic substances. The oxidized aromatics counteract oxidase activity and fatty acid oxidation, so as to bring about a state of fluctuation in oxidation, and incomplete oxidation results. The centripetal development of the endodermal walls and unsaturated nature of suberin are evidences of this fluctuation in oxidation and deposition. The oxidase system originates in the phloem. At least the organic peroxide precursors come from the phloem, and it is probable that their activators also come from the phloem. A part of the oxidase system may be blocked by the mature endodermis. The first suberin layer may be a "shock" layer which influences and helps to bring about later deposition. Oxidase activity is increased by incipient desiccation and by wounding.

THE DISTRIBUTION OF THE ENDODERMIS IN MONOCOTYLEDONOUS PLANTS.—There has not been a tabulation of the distribution of the endodermis in monocotyledonous plants since Müller's (1906) excellent survey of the literature and additions to it through

his own observations. Müller divided the plants which he and others had studied into those with stems lacking a cylinder endodermis and those with a cylinder endodermis. The extent of the endodermis was not carefully considered in subaerial and aerial stems. Early plant histologists recognized the endodermis only in those cases where there was a very conspicuous Casparian strip or a mature condition of obvious unilateral deposition. The mestome sheath or bundle sheath was considered as a distinct tissue allied to the endodermis but not a true endodermis (Schwendener, 1888). By hydrolyzing cell walls with zonite, hydrochloric acid and zinc chloride, etc., many cells, which by their appearance belong either to the cortex or sclericycle, are shown to be actually endodermal cells since the washing away of younger lamellae reveals Casparian strips. This is also true of many, but not all, mestome or bundle sheath cells of *Cyperus*, *Carex*, *Zebrina*, *Tradescantia*, and others.

Unilateral deposition is not always a good criterion for the identification of the endodermis because cells other than the true endodermis become centripetally thickened (Russow's " ϕ Zellen"; see Schwendener, 1888, or Müller, 1906). The author has found only a few instances of the absence of the Casparian strip where unilateral deposition will take place or has taken place. Hence, the Casparian strip is often an excellent guide to what constitutes an endodermal tissue both in appearance and point of origin. Unilateral deposition usually takes place in cells which have earlier developed Casparian strips. These two distinct types of deposition are almost without exception confined to the same tissue in monocotyledonous plants. The masking of the Casparian strips by later deposits has led all the early investigators to overlook some endodermal tissues and to regard them as another type of tissue. This was true of the interpretation of the mestome sheath by Schwendener (1890), Wille (1915), and others.

Physiologic position thus becomes more significant than any anatomical position with reference to stele or cortex. The critical physiologic barrier between cortical extremes on the one hand and phloem and xylem conditions on the other will give an endodermis which varies greatly in its distribution in a single plant. For example, in *Tradescantia aureo-striata*, there is a cylinder endodermis below the surface and at the same time a bundle sheath type of endodermis surrounding some internal as well as peripheral bundles. The aerial prostrate stems of this plant lack a cylinder endodermis at times so that only a bundle sheath is present, and it is not recognizable as an endodermis unless hydrolyzing agents are employed. The tissue does not serve as a guide to the anatomy of a plant so much as it does to developmental and functional conditions within tissues.

A tabulation of the distribution of the endodermis in monocotyledonous plants, as determined by the author, is presented in appendix 1. Each plant in this list was examined with a view to determining the distribution of the endodermis in aerial and sub-

aerial organs, or its distribution in aerial and subterranean portions of the same organ. As an example of the way in which each plant has been studied, the case of *Smilax* may be presented (fig. 1, 3 and 4). The cylinder endodermis (fig. 4) completely surrounds all the bundles except in the region of the surface of the ground where the endodermis becomes broken and is present only opposite the phloem in each bundle (fig. 3). Above the surface of the ground there is not a detectable endodermis.

THE STARCH SHEATH.—It is difficult to detect the presence of oxidases in the starch sheath of *Dioscorea* and *Smilax* stems. In other parts of *Smilax* plants where oxidases are present in the endodermis, the starch granules are absent. It is conceivable that oxidases and starches would not appear at the same time in the same tissue. A disappearance of starch from wounded tissue has been observed by Brieger (1924), and he found that the starch was especially strongly removed from cells having an oxidase reaction. Biedermann and Jernakoff (1924) believe that oxidases are capable of doing diastatic work. The disappearance of starch and the appearance of the endodermis having a Casparian strip is thus conceivably due to the presence of an oxidase system. Thus the nature and distribution of the oxidase system may influence endodermal expression and be a determining factor in the presence or absence of starch in the endodermis.

A definite suberic pellicle surrounds groupings of starch granules in the starch sheath of some aerial stems of *Smilax glauca* and *S. herbacea*. This starch is resistant to diastase and ptalin solutions longer than potato starch placed in the sections and longer than other naturally occurring starches in the stele. Sections heated in hydrochloric acid-zinc chloride and treated with iodine show a breaking down of the starches of the stele as indicated by the erythrodxetrin color, but starches of the starch sheath remain blue until they are heated for a longer period of time. It is thus possible that starches are retained in the starch sheath because those cells can suberize or otherwise render the starch impervious to enzymatic, hydrolytic and oxidizing agents.

THE CASPIAN STRIP.—It has long been recognized that the Casparian strip is a deposit of lignic or suberic materials on or in the radial walls of endodermal cells. The origin of the strip has not been fully explained, although it is generally agreed that fatty and related substances pass out of the stele and diffuse between the radial walls of the cells of the endodermis. These substances, it is believed, become deposited at some exact locus in the radial walls to give a strip of uniform width.

Some observations lead me to conclude that the Casparian strip has its origin as a deposit in the inner intercellular space of the endodermal cells. With an increase in the size of the cells in a radial direction the strip comes to occupy a position farther from the intercellular cavity. In the roots of *Smilax glauca* there first appears a deposit in the inner intercellular space formed by two radial walls. Later this deposit

may be found a few microns from the intercellular space, and finally it becomes permanently located about five microns from the edge of the cavity. Thus with an increase in size in a radial direction the Casparian strip comes to occupy a more central position between the radial walls. In one instance, in roots of *S. glauca*, I found another intercellular deposit, smaller than the first, developing after the first strip became permanently located five microns from its point of origin. In roots of *Iris* there is occasionally a double Casparian strip. The first one to appear has its origin near or actually in the inner intercellular cavity, and the other develops a little later at the outer intercellular cavity. The double Casparian strip occurs opposite the xylem, but not opposite the phloem. The osmotic relations in the region of the xylem, I believe, bring about the radial enlargement of endodermal cells so that they measure from two to five microns larger, in a radial direction, than do the endodermal cells opposite the phloem. As a result of the addition of new material and expansion of the walls, this, then, results in a relocation of Casparian deposits and sometimes the formation of new ones. In the roots of *Aloe* there is often an increased radial growth opposite the xylem so that the deposit is farther from the intercellular cavity in endodermal cells in this region.

After the strip becomes permanently fixed in one place, the radial walls around it, or the entire radial wall, may take on lignosuberic substances which become deposited and obscure the strip, so that it loses its identity as an intercellular deposit. It is this mature condition which probably led some of the early anatomists to the conclusion that each cell laid down a deposit on the inside of its radial walls. It is indeed highly probable that there is some internal deposition in the formation of the strip.

The irregularity in the distribution of the endodermis in monocotyledonous plants and the different types and rates of its maturation are indicative of the full significance of what may be thought of as *position effect* in tissue differentiation. The endodermis does not always occupy the same histogenic position. Casparian strips may develop in cells other than the histogenic endodermal layer, and they develop in terms of the surrounding tissues. For example, in stems of *Smilax glauca* the Casparian strips may be found running obliquely and quite irregularly around the radial walls so that the strip is actually cleft and divided in a few places. These irregular strips may occupy more than a single layer of cells, particularly in those portions of stems close to or at the surface of the ground. It is also commonly true in *Smilax* stems that the fascicular endodermal layer is not the same histogenic layer of cells that is present between the bundles as interfascicular endodermis. Thus by physiologic position a layer of cells comes to have Casparian strips and unilateral deposition.

SUMMARY

Experiments indicate that, in the roots of *Allium*, the rate and ultimate extent of the development of

the endodermis are governed, in part at least, by certain sets of environmental factors. An alternation of dry and moist conditions, accompanied by constant aeration, is apparently most conducive to the centripetal development and deposition of the walls of endodermal cells. Incipient desiccation and plasmolysis is recognized as a possible explanation for centripetal development. Several factors, such as light, temperature, salts, and organic substances, have a lesser influence on the maturation of this tissue and particularly as they may affect an oxidase system associated with the endodermis in its development.

The centripetal development of endodermal cell walls, the unsaturated nature of suberin, and the irregular distribution of the endodermis are evidences of a fluctuation in oxidation and deposition. This fluctuation is brought about by cortical, stelar and environmental factors which influence the activity, distribution, and nature of an oxidase system associated with the endodermis. Thus, a functional cuticular barrier prevents the movement of gases across the cortex; hence the oxidase and depositional precursors do not become confined to the endodermal layer but are spread throughout the cortex. If, on the other hand, the cuticle is not functional and does allow the diffusion of gases and the formation of a higher oxygen gradient across the cortex, then the oxidase system becomes confined and complete at the endodermal barrier and brings about characteristic deposition in this dermal layer.

The Casparian strip has its origin, at least in some cases, as an extracellular deposit first formed in the intercellular space, later occupying its characteristic position between the radial walls due to the radial growth of the cells.

The endodermal starch sheath is low in oxidases, which apparently accounts for the retention of starch and the absence of centripetal deposits characteristic of the endodermis. The retention of starch in the endodermis, to form a starch sheath, seems to be due, in some instances at least, to the deposition over each grain of a thin but clearly detectable pellicle of suberic substance which does not permit access of hydrolyzing enzymes to the starch. Hydrolytic agents are slower in bringing about the hydrolysis of this starch than of other starches in the plant.

Using a new definition of endodermal tissue, the distribution of endodermis has been determined in 17 families and over 90 genera and 100 species of endogenous plants.

TIFFIN, OHIO

APPENDIX

The distribution of the endodermis in stems of monocotyledonous plants.—The cylinder endodermis, modified bundle sheath and related tissues may be classified on the basis of their distribution in stems, modified stems, and leaves of monocotyledonous plants. The following categories have been es-

tablished as a result of personal observation in most cases (indicated by *), but some of the plants listed have been taken from the literature in cases where it was possible to authenticate the statements of the authors or to reinvestigate at least the genus. Authorities accredited with the original observations are listed by name and date of publication after the name of the plant whose endodermis they studied.

ENDODERMAL TISSUES PRESENT IN HORIZONTAL AND ERECT UNDERGROUND STEMS.—ALISMACEAE: **Alisma Plantago-aquatica*, *Alisma Plantago* (Sauvageau, 1891), **Sagittaria sagittifolia* (Guillaud, 1878). AMARYLLIDACEAE: **Doryanthes Palmeri*. ARACEAE: **Acorus Calamus* (de Bary, 1877, and Guillaud, 1878), **Acorus gramineus* (de Bary, 1877), **Symplocarpus foetidus*. BROMELIACEAE: **Ananas sativus*. CANNACEAE: **Canna indica*. CYPERACEAE: **Carex picta*, **Carex vulpinoidea*, **Carex vulpina*, **Carex arenaria*, *C. leporina*, *C. paniculata*, and *C. hirta* (Schwendener, 1890); **Scirpus atrovirens*, *S. cernuus*. IRIDACEAE: **Belamcanda chinensis*, *Iris florentina* (Guillaud, 1878), *Iris versicolor*. LILIACEAE: **Allium tricoccum* (prophyllar bulb connective), **Aloe chinensis* (Mangin, 1882), **Aspidistra elatior* (Chrysler, 1903), **Camassia esculenta*, **Convallaria majalis* (Mangin, 1882, and Müller, 1906), **Sansevieria Kirkii*, **Sansevieria Zeylanica* var. *aurantia*, **Veratrum Woodii*, **Yucca gloriosa* (seedling). NAIADACEAE: *Zostera marina*, and *Z. nana* (Sauvageau, 1891). ORCHIDACEAE: **Aplectrum hyemale*. PALMACEAE: **Chamaedorea elatior* (Guillaud, 1878), **Phoenix dactylifera* (seedling). TYPHACEAE: **Typha angustifolia* (Müller, 1906).

ENDODERMAL TISSUES PRESENT IN ERECT UNDERGROUND STEMS, CULMS OR SCAPES UP TO THE GROUND LINE WHERE IT DROPS OUT, OR WHERE IT DROPS OUT AS A CYLINDER ENDODERMIS TO BECOME A BUNDLE SHEATH.—AMARYLLIDACEAE: **Agave americana* var. *marginata*. BROMELIACEAE: **Ananas sativus*. COMMELINACEAE: **Tradescantia Crassula*, **T. aureo-striata*, **T. reflexa*, **Zebrina pendula*. CYPERACEAE: **Carex trichocarpa*, **Scirpus atrovirens* and others of this genus. LILIACEAE: **Allium sativum* (scape), **Allium canadensis*, **Asparagus officinalis*, **A. Sprengeri*, **Convallaria majalis* (Müller, 1906), **Hosta japonica*, **Maianthemum canadense*, **Medeola virginiana*, **Oakesia sessifolia*, **Ruscus aculeatus*, **Sansevieria carnea* (lower side of rhizome, Müller, 1906), **Smilacina racemosa*, **S. stellata* (not always), **Smilax Bona-nox* (not always), **S. ecirrhata*, **S. pseudo-china*, **S. laurifolia*, **S. lanceolata* (not always), **S. glauca*, **S. rotundifolia* (not always), **S. herbacea*, **S. hispida*, **Smilax China* (Meyer, 1881). SPARGANIACEAE: **Sparganium simplex*. ZINGIBERACEAE: **Hedychium gardnerianum*.

ENDODERMAL TISSUES PRESENT IN AERIAL PORTIONS OF ERECT, OR PROSTRATE STEMS, IN DECUMBENT AERIAL STEMS, AND IN CULMS AND SCAPES AS A CYLINDER ENDODERMIS.—ARACEAE: **Scindapsus pictus* (Müller, 1906). COMMELINACEAE: **Commelina virginica* (erect and prostrate), **Tradescantia fluminensis* (both cylinder endodermis and bundle sheath, Priestley and Scott, 1925). CYPERACEAE: **Carex picta*, **C. vulpinoidea* (stem), **Cyperus strigosus*. IRIDACEAE: **Iris versicolor*. LILIACEAE: **Asparagus asparagoides* var. *myrtifolium*, **Chlorophytum elatum*, **Medeola asparagoides* (Müller, 1906), **Smilax ecirrhata*. ORCHIDACEAE: **Epipactis pubescens*, **Vanilla planifolia* (Müller, 1906).

ENDODERMAL TISSUE PRESENT IN LEAVES BELOW THE SURFACE, AND PORTIONS OF SUBAERIAL LEAVES (EITHER AS A CYLINDER ENDODERMIS OR AS A BUNDLE SHEATH).—AMA-

RYLLIDACEAE: **Agave americana* var. *marginata*.
BROMELIACEAE: **Ananas sativus*. CANNACEAE:
**Canna indica*. IRIDACEAE: **Iris versicolor*. LILIA-
CEAE: **Allium tricoccum*, **Aloe latifolia*, **Aspidistra*
clatior, **Hosta japonica*, **Smilax* spp. (scale leaves).

ENDODERMAL TISSUES ABSENT IN SUBAERIAL STEMS WHICH
DO NOT GROW UP TO THE GROUND LINE.—ARACEAE: *Arum*
italicum, *A. maculatum* (van Tieghem, 1886), **Arum crin-*
itum, **Colocasia esculenta*. AMARYLLIDACEAE:
**Agave Parryi*, **Hymenocallis occidentalis*, **Narcissus*
Pseudo-Narcissus, **Polygonatum tuberosa*. DIOSCOREA-
CEAE: **Dioscorea Batatas*, **D. villosa*. LILIACEAE:
**Allium* spp., **Aloe latifolia*, **A. variegata*, **Camassia*
esculenta, **Gasteria verrucosa*, **Kniphofia Tuckii*, **Mus-*
cari comosum, **Nothoscordum fragrans*, **Polygonatum*
biflorum, **P. commutatum*; **Polygonatum latifolium*, **P.*
multiflorum, **P. officinale* (Chrysler, 1903); **Polygonatum*
vulgare (Guillaud, 1878); **Trillium sessile* (Chrysler,
1903); **T. recurvatum*, **T. declinatum*, **Tulipa* spp.,
**Yucca glauca*, **Y. filamentosa*. ORCHIDACEAE: **Co-*
rallorhiza maculata, **Orchis spectabilis*.

ENDODERMAL TISSUES ABSENT IN BOTH AERIAL AND SUB-
AERIAL PORTIONS OF THE STEM, SCAPE, OR CULM, AND ALSO
LEAVES.—ALISMACEAE: **Alisma Plantago-aquatica*
(scape), **Sagittaria latifolia* (scape). AMARYLLIDA-
CEAE: **Doryanthes Palmeri* (leaf), **Narcissus Pseudo-*
Narcissus (scape), **Polygonatum tuberosa*. ARACEAE:
**Aglauonema simplex* (stem), **Amorphophallus giganteus*
(scape and petiole), **Arisaema dracontium*, **A. triphyl-*
lum (scape and petiole), **Peltandra virginica* (Müller,
1906) (stem and scape), **Philodendron hastatum*; **P. Rud-*
geum (van Tieghem, 1886); **P. cordatum* (stem),
**Symplocarpus foetidus* (scape). COMMELINACEAE:
**Rhoeo discolor* (stem). DIOSCOREACEAE: **Dioscorea*
Batatas, **D. villosa* (stem). LILIACEAE: **Aloe arbo-*
rescens (stem), **A. latifolia* (leaf), **Camassia esculenta*
(scape), **Dracaena indivisa* (stem and leaf), **Erythro-*

nium americanum (Chrysler, 1903) (scape), **Lilium re-*
gale (leaf), **Muscari comosum* (leaf and scape), **Orni-*
thogalum umbellatum, **Polygonatum biflorum*, **P. com-*
mutatum (stem); **Trillium sessile* (Chrysler, 1903)
(stem); **T. recurvatum*, **T. declinatum* (stem), **Tulipa*
spp. ORCHIDACEAE: **Aplectrum hyemale* (scape),
**Corallorhiza maculata* (scape), **Habenaria flava*
(scape), **Liparis liliifolia* (scape and leaf), **Orchis spec-*
tabilis, **Pogonia ophioglossoides* (scape), **Spiranthes cer-*
nua (stem and scape). PALMACEAE: **Livistona mauri-*
tana (de Bary, 1877), **Phoenix dactylifera* (leaf).

ENDODERMAL TISSUES PRESENT ON BOTH SIDES OF THE
SCLERICYCLE.—*Clintonia umbellulata* (Chrysler, 1903),
Luzula campestris (Guillaud, 1878), **Medeola virginiana*
(stem), **Scirpus validus* (rhizome), **Uvularia perfolia-*
tum (stem).

BUNDLE SHEATH OR MESTOME SHEATH TYPE OF ENDODER-
MAL TISSUE IN AERIAL PORTIONS OF LEAF AND STEM.—**Carex*
picta, **C. trichocarpa*, **C. vulpinoides* (leaf and stem),
**Cyperus strigosus*, **Eriocaulon septangulare* (around bun-
dles in cortex but not around those inside the stele) (Solo-
mon, 1931), **Oplismenus Burmannii* (leaf), **Pennisetum*
longistylum, **P. Ruppelianum*, **P. japonicum*, **Scirpus*
atrovirens, **S. cernuus*, **S. validus* (stem and leaf), **S.*
cyperinus, **Tradescantia fluminensis*, **T. aureo-striata*,
**Zebrina pendula*. CYPERACEAE: Present in most spec-
ies (Plowman, 1906; Wille, 1915). GRAMINEAE: The
following classification is by Schwendener (1883). Leaf
bundles with a mestome sheath: *Festuceae*, *Bambuseae*,
Aenaceae, *Hordeaceae*, *Phalarideae*, *Alopecuroideae*,
Agrostideae, *Stipaceae*, *Chlorideae*, *Arundineae*, *Oryzeae*,
Panicaceae. Leaf bundles without a mestome sheath: *Andro-*
pogoneae, *Maydeae*, *Panicaceae*. I have examined several
grasses having a mestome sheath made up of cells with
Casparian strips as shown by hydrolysis. Corn and various
members of the *Andropogoneae* and *Panicaceae* do not have
cells of the bundle sheath with Casparian strips.

STUDIES OF SOUTH AFRICAN PHAEOPHYCEAE. I. ECKLONIA MAXIMA, LAMINARIA PALLIDA, MACROCYSTIS PYRIFERA¹

George F. Papenfuss

THE PRESENT paper is the first of a short series dealing with the development in culture of certain South African Phaeophyceae. The forms treated in this account are representative of three of the five families of the order Laminariales, viz., Alariaceae (*Ecklonia maxima*), Laminariaceae (*Laminaria pallida*), and Lessoniaceae (*Macrocystis pyrifera*). The results obtained agree with those of other investigators of this order. For the pertinent literature reference should be made to the papers of Kylin (1933), Hygen (1934), and Kanda (1936). The papers of McKay (1933) and Hollenberg (1939) contain valu-

¹ Received for publication July 12, 1941.

The writer wishes to express his appreciation to Professor R. S. Adamson for placing at his disposal the facilities of the botanical laboratory of the University of Cape Town where this study was made during the years 1935-1939, and to Professor Harald Kylin for granting the facilities of the botanical laboratory of the University of Lund where most of the manuscript was prepared. Dr. M. A. Pocock kindly prepared the photographs reproduced in this paper. During the course of the study, financial assistance was obtained from the following sources: the James Buchanan Johnston Scholarship of the Johns Hopkins University, a University Research Scholarship of the Research Grant Board of South Africa, and a grant from the Carnegie Corporation of New York provided through the University of Cape Town.

able information on the process of fertilization, and the former author gives a good account of the chromosomal cycle in the life history of *Pterigophora californica*.

METHODS.—The culture methods followed were those used by Kylin (1933) and others. Fertile parts of the plants were kept out of water for several hours or over night in covered glass jars. Pieces of the material were then placed in glass dishes containing filtered sea water and slides arranged on end along the sides of the dishes. After a period ranging from about thirty minutes to several hours, depending upon the number of zoöspores that had become attached to the slides, the latter were removed, all spores wiped from the one surface and the edges, and filtered sea water poured over the slides in order to wash off as many diatoms as possible. The slides were then placed on end in glass tumblers containing the nutrient solution,² the surface containing the spores facing the side of the tumbler. The tumblers were covered with glass dishes and placed in front of a southeast window in an unheated basement room, precaution being

² The culture fluid used was the one employed by Schreiber (1930). It consists of: NaNO_3 , 0.1 gr.; Na_2HPO_4 , 0.02 gr.; distilled water, 50.0 cc.; sea water, 1,000.0 cc.

taken that they were at no time exposed to direct sunlight. The nutrient solution was not renewed except when the cultures were kept for many months. In certain instances distilled water only was added at intervals to replace the water lost by evaporation. Desired stages of the sporelings were fixed in position on the slides with Flemming's weak solution for a period of five to ten minutes. The fixative was removed by rinsing the slides in sea water. A few drops of glycerine were then added to the slides and the lat-

Fig. 1. *Ecklonia maxima*, habit of plant, about 1/20 nat. size.

ter kept in covered boxes for several weeks to allow the glycerine to become concentrated. Cover-glasses were then placed on the slides and the latter sealed and stored for future study. In such preparations the sporelings retain their normal form and most of their color; no staining is necessary unless it is desired to study the cytology of the plantlets.

ECKLONIA MAXIMA (OSBECK) PAPENF.—*General remarks*.—This plant has been known for a long time as *Ecklonia buccinalis*, but it was recently pointed out by Papenfuss (1940) that the specific name *maxima* has priority.

The known South African distribution of *E. maxima* extends from Port Nolloth on the west coast

(Bright, 1938) to a place, Papenkuilsfontein, about six miles west of Cape Agulhas on the south coast, where the writer found it growing in abundance in 1937. This distribution is not continuous, however, for the species is absent, or is represented only by occasional stunted individuals, along the northern and the greater part of the western shores of False Bay. The absence or scarcity of *E. maxima* in this region is owing no doubt to the high sea temperatures that prevail there during the summer months.³ Isaac (1938), who has studied the temperature conditions of the South African coastal waters, states (p. 25): "It is safe to assume that, where more or less normal sized *Ecklonia buccinalis* grows, the mean annual temperature does not exceed about 14.6°C." The high temperature conditions that eliminate *E. maxima* from the flora of the northern and western parts of False Bay are apparently less marked or do not obtain along the central and southern parts of the eastern shore of this bay and in consequence the species reappears at certain stations along this coast, starting at the mouth of the Steenbras River, and extends eastward beyond False Bay as far as the locality near Cape Agulhas referred to above.⁴

In addition to South Africa, *E. maxima* has been reported from the following parts of the world: St. Paul Island in the southern ocean (Grunow, 1867), Tristan da Cunha (Kolben, 1719), Falkland Islands (Bory, 1826), Chile (Postels and Ruprecht, 1840).

The presence of *E. maxima* at St. Paul is not improbable, as this island has a number of other marine algae in common with South Africa. The occurrence of the species at any of the other localities is extremely doubtful, however. The record for Tristan da Cunha is based on Kolben's (1719, p. 298) statement that the plant was observed floating in the vicinity of the island during his voyage to South Africa in 1705. It is not clear from Kolben's account, however, that he actually was near Tristan da Cunha. According to Dr. E. Baardseth, algologist of the recent Norwegian expedition to Tristan da Cunha, the species does not occur at the island (personal communication). The record for Falkland Islands is based on the plant that Bory (1826, p. 594) described as *Laminaria flabellum*, a species that he (Bory, 1828, p. 99) later considered as a variety of *E. maxima*. Certain subsequent authors have also regarded *L. flabellum* Bory as being identical with *E. maxima*, but Hooker (1845, p. 160) and others are doubtful of the correctness of this interpretation. The Chilean record of Postels and Ruprecht (1840, p. 3) is based on specimens that were secured from the drift. Judging from their figure (plate 11), it seems very doubtful that the plant is *E. maxima*. The figure shows a specimen in which the pinnae are split

³ For a discussion of the factors that cause these high temperatures in this part of False Bay, see Isaac (1937a, pp. 658-659).

⁴ De Toni (1889, p. 790; 1895, p. 358) refers to a specimen of *E. maxima* in Herb. Kew that came from Algoa Bay. If this record is correct the specimen must have been obtained from the drift, as *E. maxima* does not grow in this region.

longitudinally to the base into several segments, a feature that I do not recall having seen in *E. maxima*.

In the juvenile state, the thallus of *E. maxima* consists of a simple, somewhat elongated, blade borne on a stipe. In slightly older stages pinnae develop along both margins of the blade, as will be seen from the youngest specimen in figure 1. The pinnae are initiated in the meristematic region at the base of the

The sori form broad elongated patches on both surfaces of the pinnae. Fertile plants were obtained during all months of the year but March, for which month the writer has no field data on this species.

Development of gametophyte.—The zoöspores like those of most other Laminariales lack an eyespot and exhibit no phototactic response. In this connection, it is of interest to note that in the laminarian

primary blade and are progressively shifted upward by elongation of the latter. Later the distal portion of the primary blade is worn away and the pinnae become aggregated in a dense cluster immediately above the transition region (fig. 1), the older pinnae continually wearing away and new ones being initiated. In older plants, the stipe becomes hollow and its terminal portion becomes inflated, forming a large float. Mature plants may attain a length of seven meters or more from base of stipe to tips of longest pinnae.

Eisenia arborea the zoöspores show no reaction to light even though they possess an eyespot (Hollenberg, 1939).

After a period of motility ranging from a few minutes to several hours, the zoöspores come to rest, assume a rounded form, and secrete a wall about themselves (fig. 2). Germination sets in shortly afterward and in cultures that are twenty-four hours old many germlings may have well-formed germ tubes, and the single chromatophore may have divided once (fig. 3). As development continues, the chromato-

phores and most of the cytoplasm migrate into the terminal portion of the germ tube; and in cultures that are three days old this portion of the tube usually has been delimited by a cross wall from the spore case (fig. 4). At this time the chromatophores usually have undergone further division. During the succeeding seven to ten days, growth is more or less limited to enlargement, few additional cells being formed. In cultures that are fifteen days old, it is possible, however, to distinguish between female

tension which serves as the apical portion of the oögonium (fig. 10). The oögonia are readily recognizable by their dense content and by the fact that the cytoplasm pulls away from the wall. When mature the egg is extruded through a rupture that arises at the apex of the oögonium (fig. 10). A small amount of cytoplasm frequently remains in the oögonium. The extruded egg forms a spherical naked protoplast at the mouth of the oögonium (fig. 11), where it usually remains in position. The chromatophores

Fig. 21-24. *Ecklonia maxima*.—Photomicrographs of plants grown in nutrient solution.—Fig. 21. Male gametophyte, with portion of female at the lower end, $\times 200$.—Fig. 22. Male and female gametophytes, and several young sporophytes, $\times 200$.—Fig. 23. Female gametophyte with young sporophytes, $\times 200$.—Fig. 24. Young sporophyte, $\times 85$.

(fig. 5) and male (fig. 6) gametophytes, the female plantlets being of a greater diameter than the male. Not infrequently male gametophytes of this age may have formed the first branch and consist of a total of six cells. Subsequent growth continues at a comparatively rapid rate and in cultures that are twenty-five days old the male and female plantlets have assumed the form shown in figures 7 and 8, respectively. In male gametophytes of this age, the cells, especially the terminal ones, generally contain fewer and larger chromatophores than do those of the female plantlets. At this stage the first signs of the differentiation of reproductive organs, especially of the oögonia, may be observed; and in cultures that are thirty-five days old young sporophytes may already be present, although reproductive organs and sporophytes are usually not formed in abundance until the gametophytes are forty to fifty days old.

The oögonia (fig. 9) develop from terminal or from intercalary cells. When an intercalary cell is transformed into an oögonium it forms a lateral ex-

of the egg retain their identity and can be recognized during the entire maturation period of the egg (fig. 9-11).

Male gametophytes (fig. 21, 22) differ from female ones in being slenderer and much more profusely branched. The antheridia (fig. 12) are formed in clusters at the tips of the branches or as outgrowths from intercalary cells. Young antheridia may be distinguished from vegetative cells by their denser cytoplasmic content. As the antheridium matures, the cytoplasm withdraws from the wall and appears as a homogeneous brownish matrix. Each antheridium apparently forms but one spermatozoid.

Development of sporophyte.—Fertilization of the egg was not observed but the first noticeable change which presumably follows this process is the formation of a wall about the zygote (fig. 13). The zygote then elongates and ultimately divides transversely (fig. 14). The next few walls are also in a transverse plane (fig. 15, 16). Longitudinal walls then set in, starting at the terminal end (fig. 17, 18), and

as a result growth takes place in two planes, giving rise to a somewhat elongated monostromatic sporophyte (fig. 23). The plantlet shown in figure 19 has formed its first rhizoid. At times a second rhizoid may have been formed at this stage but usually it is formed considerably later. The rhizoids are always nonseptate and are usually unbranched; branched rhizoids were but rarely observed. The chromatophores present in a young rhizoid later degenerate.

The young sporophytes become distromatic at a comparatively early stage. The first cells to divide periclinally are those in the basal region, the part

prevail in these regions during the summer months (cf. Isaac, 1937b, p. 146).

In addition to South Africa, *L. pallida* has been reported from St. Paul Island in the southern ocean (Grunow, 1867, p. 51); the Canary Islands, the Atlantic coast of Morocco, the coasts of Portugal and northwestern Spain, and the southwestern part of the Mediterranean (cf. Dangeard, 1936, p. 101; Feldmann, 1934, p. 13). The plants from St. Paul probably are of this species, but those from the northeastern Atlantic and the western Mediterranean have been shown by French algologists to be of a distinct

Fig. 25-28. *Laminaria pallida*.—Fig. 25-27. Stages in development of macroscopic phase of sporophyte.—Fig. 28. Young sporophytes of plants cultured in sea water. Fig. 25, about 1/12 nat. size. Fig. 26, about 1/33 nat. size. Fig. 27, about 1/30 nat. size. Fig. 28, $\times 200$.

destined to form the stipe. The sporophytes shown in figures 20 and 24 had already become distromatic in the basal region.

The development of gametophytes and young sporophytes described above is that which occurs during spring and summer. During winter months the gametophytes are considerably slower in attaining sexual maturity. This is in agreement with the findings of several other investigators of the Laminariales.

LAMINARIA PALLIDA GREV. EX J. AG.—*General remarks.*—The binomial *Laminaria pallida* is a MS. name of Greville under which the species was first described by J. Agardh in 1848.

The known South African distribution of *L. pallida* extends from the southwestern part of the Cape Peninsula to Port Nolloth (Bright, 1938) in the northwestern part of the Cape Province. The species increases in relative frequency towards the north (Isaac, 1937b; Bright, 1938), in which direction there is a gradual decrease in sea temperatures. The absence of the species along the east coast of the Cape Peninsula and points farther east is undoubtedly associated with the higher sea temperatures that

species which was described by La Pylaie in 1824 as *Laminaria ochroleuca* (cf. Hamel, 1931-1939, p. 303).

In the juvenile state *L. pallida* consists of a simple blade (fig. 25). The blade splits longitudinally at an early stage into several deep segments (fig. 25, 26) which, as growth continues, in turn become divided. In the mature state (fig. 27), the plant may attain a length of about 5 meters. Fertile plants were obtained during all months of the year but March, for which month the writer has no data. The sporangia form extensive sori on both surfaces of the segments of the blade. The histology of the sporophyte of *L. pallida* has been studied by Dangeard (1936).

Development of gametophyte.—In structure and behavior the zoöspores agree with those of *Ecklonia*. Stages in the development of the gametophytes and sexual organs are shown in figures 29 to 36. In *Laminaria pallida* the spore case is but seldom cut off by a cross wall from the germ tube, as in *Ecklonia* (compare fig. 4 to 6 and 31, 32). The plantlets do not usually become fertile until they are at least one month old; but at times, as shown in figure 34, sexual

organs develop on younger gametophytes. In older plants the antheridia occur in clusters, as in *Ecklonia*. The oogonia develop, as in *Ecklonia*, from intercalary as well as terminal cells of the female gametophytes (fig. 35).

Development of sporophyte.—The early stages in the development of the sporophyte will be seen from figures 37 to 42 and 28. In many sporophytes of the stage shown in figure 42, or even in less advanced ones, the basal cell will have formed the first rhizoid. Additional rhizoids are formed later from

coming fertile. The gametophytes in the sea water cultures were much smaller, however, than those in the nutrient solution. The sporophytes, on the contrary, appeared normal as will be seen from those of *L. pallida* shown in figure 28. The further development of the sporophytes was soon arrested, however, and they finally died without having attained as advanced a stage as did those developing in nutrient solution. The early development of reproductive organs in sea water cultures is undoubtedly owing to a starvation effect.

Fig. 29-42. *Laminaria pallida*.—All figures are camera lucida drawings of plants grown in nutrient solution.—Fig. 29. Rounded zoöspores, $\times 990$.—Fig. 30. Gametophyte, 2 days old, $\times 990$.—Fig. 31. Same, σ , 14 days old, $\times 990$.—Fig. 32. Same, ρ , 14 days old, $\times 990$.—Fig. 33. Same, ρ , 25 days old, $\times 440$.—Fig. 34. Same, σ with antheridia, 25 days old, $\times 650$.—Fig. 35. Portion of female gametophyte with two oogonia, one in the process of extrusion, $\times 440$.—Fig. 36. other cells in the basal region. As in *Ecklonia*, the rhizoids are nonseptate and but rarely branched. The young sporophyte shown in figure 42 had become distromatic throughout its basal half.

In connection with the development of gametophytes and young sporophytes, it is of interest to note that Harries (1932, p. 925), working on *Laminaria digitata*, *L. saccharina*, and *L. Cloustoni*, found that "... no growth occurs where the initial supply of sea water is not renewed and nutrient materials are not supplied." In the present study it was found, however, that the gametophytes of both *Laminaria pallida* and *Macrocystis pyrifera* will become fertile in sea water alone. Thus, for example, on October 29, 1935, four cultures were made of zoöspores from the same parent plants of *L. pallida* and *M. pyrifera*. In two of the cultures the fluid consisted of sea water only while nutrient materials were added to the other two. The vessels were placed next to one another some distance away from a window and the fluid was not changed. In the sea water cultures, sporophytes had been formed in both species after twenty-five days (November 23, 1935), while the gametophytes in the nutrient solution as yet showed no sign of be-

coming fertile. In the course of this study it was found that in certain nutrient solution cultures of all three species, the gametophytes form but few reproductive organs or remain entirely sterile. Thus, a culture of *L. pallida* that was started on November 20, 1935, was still growing actively on December 3, 1936, when it was discarded, without having become fertile. Other cultures made during the same month and year formed reproductive organs. In another culture of *L. pallida* that was started on May 14, 1936, a few sporophytes had developed after twenty-seven days (June 10) but no additional sex organs were formed, and the culture was finally discarded on December 3, 1936. In none of these cultures was the nutrient solution renewed; only a small amount of distilled water was added from time to time to replace the water lost by evaporation.

These results are comparable to those obtained by Hollenberg (1939, p. 38), who states: "When gametophytes of *Eisenia arborea* in the cultures once take on an elongate sterile form, I have been unable to induce the formation of sex organs, although I have tried low temperatures ($2-3^{\circ}\text{C}.$) and changes

in light intensity as well as changes in nutrient concentration."

MACROCYSTIS PYRIFERA (L.) C. AG.—*General remarks*.—This plant has attracted the attention of naturalists and navigators since early times (cf. Hooker, 1845, p. 157). The species was described by Linnaeus in 1771 from specimens that were collected by König on his voyage to India. The source of König's plants, as given by Linnaeus, is "*Mare Aethiopicum*." Setchell (1932) attributes this name to certain Antarctic islands, but Papenfuss (1940) recently pointed out that according to old maps it applies to that part of the Atlantic which lies opposite Africa from the coast of Guinea southward.

fera in South Africa, it becomes evident that the area of distribution is limited to a comparatively small region lying approximately between latitudes 33° 24'S. and 34° 8'S. According to data presented by Isaac (1937a), the minimum and maximum annual sea temperatures of this region may be taken as varying between approximately 12° and 16°C. In consideration of the fact that in Antarctic regions *M. pyrifera* thrives at temperatures much lower than these (cf. Setchell, 1932, p. 446) and that along the west coast of South Africa there is a gradual decrease in sea temperatures from south to north, it would be expected that the species would extend northward for a considerable distance beyond Das-

Fig. 43-57. *Macrocystis pyrifera*.—All figures are camera lucida drawings of plants grown in nutrient solution with the exception of figure 57, which is of a plant grown in sea water.—Fig. 43. Immature oogonium, $\times 440$.—Fig. 51. Extruded egg, $\times 440$.—Fig. 52, 53. Antheridia, $\times 990$.—Fig. 54. Zygote, $\times 440$.—Fig. 55-57. Early stages in development of sporophyte, figure 57 showing a sporophyte developing within the oogonium from an unextruded egg, $\times 440$.

As is well known, *Macrocystis pyrifera* has an extensive distribution, which has been discussed and mapped by Setchell (1932). As will be seen from Setchell's account this area is inhabited in part by a second species of *Macrocystis*, *M. integrifolia* Bory.

The South African distribution of *M. pyrifera* is limited to the southwestern part of the Cape Province, extending from the Olifants River in the north to Cape Point in the south (i.e., approximately between latitudes 31° 42'S. and 34° 20'S.). It is likely, however, that the Olifants River record (Drège, 1843, pp. 107, 200) is based on a specimen that was cast ashore, in which event the northernmost known record of occurrence would be Dassen Island (Isaac, 1937b, p. 142). The southernmost locality, Cape Point (Delf and Levyns, 1926, p. 503), also requires confirmation. The species does, however, occur at Slangkop, a station in the central west coast of the Cape Peninsula. Assuming then that Dassen Island and Slangkop are the northernmost and southernmost limits of occurrence, respectively, of *M. pyri-*

sen Island. As yet there is no evidence, however, to support this supposition.

In South Africa *M. pyrifera* is a shallow water plant, inhabiting localities that are protected from the full force of the waves. The plants are much shorter than those recorded from certain other parts of the world and probably never exceed 15 meters in length, a dimension in excess of any of the specimens seen by the writer.

The morphology of the sporophyte of *M. pyrifera* has been the subject of a number of studies, the most important recent ones being those of Skottsberg (1907) and of Setchell (1932).

Fertile plants were obtained by the writer during all months of the year with the exception of April and June. This gap is filled, however, by Delf and Levyns (1926), who obtained fertile specimens during April, and by Levyns (1933), who secured some in June.

In South African plants, the sori seem to be confined to the smooth or but slightly wrinkled pinnae of

the basal short branches, whereas in the Falkland Islands, Skottsborg (1907) observed sori also on the wrinkled pinnae of long branches. The sori are formed on both surfaces of the pinnae and may occupy extensive areas or occur as isolated patches.

Development of gametophyte.—The development of the gametophyte and the early stages of the sporophyte have been studied previously by Brandt (1923), Delf and Levyns (1926), and Levyns (1933). None of these studies was complete, however, and certain statements required substantiation. Brandt misinterpreted the oogonium and referred to it as a proembryo.

In structure and behavior the zoöspores agree with those of *Ecklonia*. According to Delf and Levyns

As stated in the section on *Laminaria pallida*, the gametophytes when cultured in sea water become sexually mature within twenty-five days. Levyns (1933) obtained young sporophytes in a sea water culture that was seventeen days old (June 8–25). Gametophytes grown in nutrient solution are slower in attaining sexual maturity. In such cultures the writer has observed the differentiation of oogonia thirty-seven days after the culture was started (during spring), while in a culture that was forty-four days old reproductive organs were abundant (fig. 58) and sporophytes had been formed.

Development of sporophyte.—The development of the young sporophyte (fig. 54–56, 59) is in accordance with that of other members of the order. In

Fig. 58, 59. *Macrocyctis pyrifera*.—Fig. 58. Male and female gametophytes, the latter with extruded eggs, of plants cultured in nutrient solution, 44 days old, $\times 200$.—Fig. 59. Gametophytes and young sporophytes of plants cultured in sea water, 25 days old, $\times 200$.

(1926), the zoöspores of *Macrocyctis pyrifera* appear to be of two sizes; but the writer, in agreement with Levyns (1933), found them to be of the same size.

Stages in the development of the gametophytes and sexual organs are shown in figures 43 to 53 and 58. In the majority of gametophytes the spore case is emptied of cytoplasm, as shown in figure 45, but not infrequently this cell remains functional (fig. 44). The oogonia and antheridia are formed as in *Ecklonia*.

The statements of Delf and Levyns (1926) regarding the sexual nature of the gametophytes are contradictory. In their figures 1a and 1b are shown plantlets that were believed to be male and female gametophytes, respectively, while on page 505 they state: "The empty thick-walled cells at the base of the young sporophyte (fig. 2) seem to indicate a bisexual gametophyte. . . ." These authors obviously mistook empty oogonia for empty antheridia. Brandt (1923) makes no reference to male gametophytes, while Levyns (1933) describes and figures them correctly.

figure 57 is shown a two-celled sporophyte which was formed from an egg that had not been extruded from the oogonium. The retention of the ripe egg in the oogonium is an abnormal condition that was frequently observed in plants cultivated in sea water only and is probably associated with the general lack of vigor of such plants. In this connection attention may be drawn to the statement of Levyns (1933, p. 352) that: "In *Macrocyctis* the egg is fertilized within the oogonium, and the process of extrusion takes place *after* the zygote has been formed." The writer's observations indicate that Levyns, who had sea water cultures only, was misled in believing that the retention of the ripe egg in the oogonium represents the normal condition in *Macrocyctis*. Moreover, her conclusion that extrusion occurs after fertilization is probably based, judging from her figures, on observations of different eggs—some that were not extruded, some that were partially extruded, and others that were completely extruded. The writer's sea water cultures showed similar stages but the presence of young sporophytes within the oogonia (fig. 57) indicates that an unextruded egg remains in the oogonium even

after fertilization. With respect to the undischarged eggs, it is highly probable, however, that a rupture of the oögonial wall precedes fertilization and that the spermatozoid enters through this break. The body lying next to the partially extruded egg in Levyns' figure 8 probably does not represent the remains of the spermatozoid, as the author believes, at least not the one which fertilized the egg, since it has been shown by McKay (1933, pl. 14, fig. 2) and by Hollenberg (1939, fig. 22–25) that the spermatozoid completely coalesces with the egg during fertilization.

Finally, it may be noted that *Chorda Filum* is the only member of the Laminariales in which the ripe eggs are known to be normally only partially extruded from the oögonium (Kylin, 1933; Kanda, 1938). *Chorda*, however, differs from other Laminariales also in several other features, such as in the formation of hairs and of septate rhizoids by the young sporophytes.

SUMMARY

Ecklonia maxima, *Laminaria pallida*, and *Macrocystis pyrifera* inhabit the colder west coast waters of South Africa, *E. maxima* being the only species

of the three that extends eastward beyond the Cape of Good Hope.

The geographical distribution of *E. maxima* and *L. pallida* is discussed, and it is pointed out that St. Paul Island in the southern ocean is probably the only authentic extra-South African station for these species.

Fertile sporophytes of the three species were secured during all seasons of the year. The development of the gametophytes and the young sporophytes is similar to that described for other Laminariales.

In agreement with the observations of Levyns (1933) and in contrast to those of Delf and Levyns (1926), it was found that the zoöspores of *Macrocystis* are not of two distinct sizes.

In nutrient solution cultures the eggs of *M. pyrifera* are extruded from the oögonia, indicating that the retention of the egg in certain oögonia of plants cultured in sea water only is an abnormal condition and not a characteristic feature of this species, as was believed by Levyns (1933).

PARASITISM AMONG THE CHYTRIDS¹

John S. Karling

FUNGUS PARASITES of other fungi are fairly common in nature, but parasitism between closely related genera and species is comparatively rare. This is particularly true in the order of simple fungi known as the Chytridiales where only a few cases of parasitism have been found. Up to the present time only nine species parasitic on other chytrids have been reported, as is shown by the following list:

Olpidiopsis (?) *Sphaeritae* comb. nov. on *Sphaerita endogena* (Dangeard, 1889).

Pleotrachelus paradoxus on *Rhizophidium distinctum* (Petersen, 1905).

Tylochytrium dangeardii comb. nov. on *Saccomyces dangeardii* (Serbinow, 1907).

Phlyctocytrium Synchytrii on *Synchytrium endobioticum* (Köhler, 1924).

Rozella Polyphagi on *Polyphagus Euglenae* (Sparrow, 1936a).

R. maximum on *Chytridium Polysiphoniae* (Sparrow, 1936b).

Rozella sp. on *Rhizophlyctis rosea* (Ward, 1939).

R. Cladochytrii on species of *Cladochytrium* and *Nowakowskiella* (Karling, 1941).

R. Endochytrii on *Endochytrium operculatum* (Karling, l.c.).

All of these species are parasitic on chytrids, which in turn parasitize amoebae, algae, and higher plants or live saprophytically in dead vegetable debris. Of the nine species listed above, none attack hosts which belong to the same genus as the parasite, and only one, *T. dangeardii*, occurs on a host within the same family. Two of the parasites are extramatrical, eucarpic, and rhizidiaceous, while the remainder are intramatrical, holocarpic, and *Olpidium*-like. To this latter group may now be added another species of *Rozella* which has recently been found in *Rhizophlyctis petersenii*.

Rozella is of particular interest to pathologists because all of its species are parasites of higher Oomycetes and chytrids and cause local hypertrophy or septation of the host hyphae. Although species of this genus have been recognized for more than a half century, very little is known about their development within the host. Nonetheless, students of *Rozella* divide the species into two groups on the basis of their development within the host and the reactions induced. Species in the so-called "sporangium-group" cause marked local hypertrophy of the host hyphae, and each thallus forms a single sporan-

gium or resting spore. In the "septigena-group" the thallus or plasmodium is reported to segment and give rise to a linear series of sporangia which mature in basipetal succession. The presence of the parasite also causes slight hypertrophy and leads to the formation of cross walls in the host hyphae, whereby the successive sporangia are separated from each other. However, no conclusive cytological data have been presented to support these distinctions. Cornu (1872) reported that after entry into the host the zoospores become indistinct and obscure but form a plasmodium in the center of host hyphae. While he found no conclusive evidence to support his view, he nevertheless believed it more plausible that the successive sporangia in *R. septigena* originate by fragmentation of the plasmodium than from multiple infection in basipetal succession. Fischer (1882) asserted that in the *R. septigena*, the type species of the "septigena-group," the parasite loses all individuality as its protoplasm mixes with that of the host and forms a plasmodium, which, however, eventually consumes the host constituent. At maturity this plasmodium divides into a number of portions which become permanently separated through the formation of cross septa by the host. Later, each portion forms one sporangium which completely fills the delimited segment of the host hypha. While it is true that the parasite usually becomes largely invisible in the relatively dense protoplasm of the host and gives the appearance of having fused with the latter, neither Fischer nor subsequent workers have clearly demonstrated its miscibility with the host protoplasm. Dangeard's (1890) figures of thalli from fixed, sectioned, and stained material, however, suggest that the host protoplasm is consumed completely by the time the thalli are mature.

Likewise, it is not certain whether the plasmodium develops from a single zoospore or is formed by the union of several protoplasts within the hosts. Butler (1907) upheld the latter view from his study of species in the "sporangium-group" but did not support it by cytological data. Furthermore, the development of the wall around the mature parasite in both groups is not clearly understood. Following Cornu's early description of the process, all students of *Rozella* have reported that as the sporangium wall of the parasite develops, it becomes fused so closely with that of the host that the two are indistinguishable and cannot be separated. While this type of development seems to occur, its successive stages have never been described or figured. In addition, our knowledge

¹ Received for publication July 23, 1941.

of the nutrition of *Rozella* is limited and confusing. As the parasite matures, masses of granules and bodies appear in the central vacuole which look like extraneous food or waste material extruded by the protoplasm in dedifferentiating for sporogenesis. The presence of such material suggests that *Rozella* is capable of engulfing and feeding on masses of host protoplasm and, like *Woronina glomerata* and protoomyxean species, discards the accumulated waste products before forming zoospores or resting spores. If this occurs, it is obvious that the nutrition of *Rozella* differs radically from that of other genera of the family Olpidiaceae in which it is now included.

From the taxonomic and systematic standpoints, also, *Rozella* has been greatly confused. Cornu described the zoospores as posteriorly uniflagellate in both groups, but later in *R. septigena* and *R. simulans*, Fischer figured them as biflagellate and heterocont. Fischer was thus confronted with *Rozella* species of two types, but he (1892) solved this difficulty to his satisfaction by erecting a new genus, *Pleolpidium*, for the "sporangium-group" species with posteriorly uniflagellate zoospores and retained Cornu's *Rozella* for the biflagellate, heterocont, "septigenous" species. It is to be noted and emphasized in this connection that Fischer's (1882) statement concerning the number, relative lengths, and position of the flagella does not relate specifically to *R. septigena* and *R. simulans*. It was applied in general to the zoospores of *Olpidiopsis*, *Woronina*, and *Rozella* as a group, and Fischer thus asserted that the zoospores of these genera are exactly alike in this respect. *Pleolpidium* was accordingly included in the family Monolpidiaceae (Olpidiaceae), while *Rozella* was placed among the Merolpidiaceae (Synchytriaceae). Fischer's disposition of these genera was accepted by Schroeter (1897), but Minden (1911), Gaumann (1926), Gaumann and Dodge (1928), and Fitzpatrick (1930) shifted *Rozella* to the family Woroninaceae and placed it next to *Woronina*. The inclusion of *Rozella* in the Woroninaceae was generally accepted by chytridologists until Foust (1937) discovered a septigenous *Rozella* species with posteriorly uniflagellate zoospores in *Allomyces arbuscula*, and, in 1938, Sparrow proposed the retention of *Rozella* in the original sense of Cornu and the suppression of *Pleolpidium* to the status of a synonym of *Rozella*. Nonetheless, there still remains the question of Fischer's biflagellate *R. septigena* and *R. simulans*. Fischer's observations on the occurrence of this species and the number and relative lengths of the flagella were later confirmed by Minden (1911) and Tokunaga (1933) for *R. simulans*. The latter worker, however, figured and described the two unequal flagella as being anterior instead of lateral in position, which raises the question of whether or not he was studying Fischer's species. In the event that Fischer, Minden, and Tokunaga were correct in their observation, it will be necessary to segregate these species in a new genus. Further complications have arisen by the discovery of parasitic species which resemble very closely members of the "sporangium-

group" of *Rozella* but which also possess biflagellate zoospores. Butler (l.c.) and Miss Waterhouse (1940) described them as being *Pleolpidium*-like but did not dispose of them taxonomically. Obviously, provision must be made for these species also.

These are some of the outstanding problems which remain to be solved and which make *Rozella* particularly intriguing to cytologists, pathologists, and systematists. The solution of many of these problems depends largely upon cytological study of fixed, sectioned, and stained preparations, and while such studies on *Rozella* may seem relatively simple and easy, they involve unusual difficulties. In the first place, the parasite is very minute in the early developmental stages, and secondly, it usually does not occur in epidemic abundance and thus provide sufficient material for fixing, embedding, and staining. Furthermore, except for the higher Oomycetes, its hosts are usually short-lived, and it is, therefore, extremely difficult to keep the parasite in culture.

In view of the many problems which remain unsolved in relation to *Rozella*, a more intensive study was undertaken of *R. Cladochytrii* and *R. Endochytrii*, two parasites of chytrids which have been previously described by the author (1941) in a brief paper on Texas chytrids. The present paper is the result of this study and relates primarily to the host range, pathogenicity, and development of these species.

ROZELLA CLADOCHYTRII.—*Host range and effect on hosts.*—This species was first observed in the sporangia and intercalary enlargements of the rhizomycelium of *Nowakowskiella profusum* which was growing on cellophane in charcoal water. As soon as its parasitic nature was recognized, inoculation experiments were started to determine its host range and pathogenicity to other chytrids and filamentous fungi. Fortunately at this time, the author had on hand pure and mixed cultures of several chytrids, and it was comparatively easy and simple to test their susceptibility to the parasite. Bits of corn leaves, cellophane, and hemp seeds were inoculated with the fungi to be tested and were placed in Petri dishes containing charcoal water. To these cultures were subsequently added fragments of cellophane and corn leaves containing the parasitized rhizomycelium of *N. profusum*.

Microscopic examinations of these cultures were made daily, and within a period of six to eighteen days *R. Cladochytrii* had infected *Nowakowskiella ramosum*, *N. elegans*, *Cladochytrium replicatum*, *C. hyalinum*, and *C. crassum*. On the other hand, *Endochytrium operculatum*, *Rhizophlyctis petersenii*, *Rhizophidium globosum*, *Olpidium gregarum*, *Catenochytridium carolineanum*, *Diplophlyctis intestina*, *Entophlyctis heliomorpha*, *E. texana*, *Saprolegnia* sp., *Achlya* sp., and *Pythium de Baryanum* were not attacked and have remained healthy. Of the susceptible hosts only *N. profusum* and *C. replicatum* were severely parasitized. A few infected sporangia and intercalary swellings of *N. elegans*, *N. ramosum*, *C. hyalinum*, and *C. crassum* were found, but in no in-

Fig. 1-24. *Rozella Cladochytrii*.—Fig. 1. Portion of infected rhizomycelium of *N. profusum* with thalli and sporangia of *R. Cladochytrii* at A, B, C, F, and G.—Fig. 2, 3. Obclavate zoospores.—Fig. 4, 5. Biflagellate zoospores.—Fig. 6. Tri-

stance did the infection attain epidemic proportions in these hosts. Present data accordingly suggest that *R. Cladochytrii* may be limited in host range to saprophytic species of the Cladochytriaceae. Unfortunately, species of *Catenaria*, *Urophlyctis*, *Physoderma*, etc., were not available for infection tests.

The effect of *R. Cladochytrii* on its hosts varies considerably. In the case of *N. profusum* infected sporangia and intercalary enlargements may be only slightly hypertrophied or up to 200 per cent larger than normal. The tenuous portion of the rhizomycelium immediately adjacent to infected sporangia may also become slightly or greatly enlarged, as is shown at D and E, respectively, in figure 1. In another instance the hypertrophied portion measured 25 μ in diameter, although it was not directly parasitized. While the hypertrophy and distortion is usually localized, in exceptional cases the entire rhizomycelium may be involved and become hypertrophied. *Rozella Cladochytrii* differs thus from other known species of the genus by its ability to cause hypertrophy of cells and organs which are not directly parasitized. Septation of parasitized filaments in the region of infection, such as is caused by *R. septigena* and *R. Allomyces*, has never been observed in our material. No cases of marked hypertrophy of the rhizomycelium of *N. ramosum*, *N. elegans*, *C. hyalinum*, and *C. crassum* have been found. In these species, however, infection was limited, and it was accordingly difficult to determine how extensive and conspicuous hypertrophy may become in these hosts. In *C. replicatum*, on the other hand, the effect of the parasite was quite evident. The degree of hypertrophy was in general slight, but thickening of the cross septa and lateral walls at the base of infected sporangia and spindle organs (fig. 17-19) frequently occurred. In some cases these thickenings were as marked as those caused by *R. Rhipidii* and *R. Apodyae* (Cornu, 1872) in their respective hosts. In addition, the exit tubes of infected sporangia often become elongated, branched, and distorted (fig. 15, 18), while the formation of golden-red refringent globules in the sporangia, characteristic of this species, is usually completely inhibited. As a result, parasitized thalli are hyaline and appear markedly different from normal ones.

Infection.—Infection occurs most abundantly when the rhizomycelium is young and growing vigorously, but it may also take place when the host is comparatively old. While infection of full-grown sporangia has not been observed, it probably occurs, because parasitized sporangia with fully developed opercula may often be found. *Nowakowskiella profusum* is more favorable than the higher Oomycetes for the study of infection and development of the parasite. When thin flakes of cellophane or lens

paper are used as substrata, the rhizomycelium grows out into the surrounding water, where infection may be studied under very high magnifications. Furthermore, the tenuous filaments are relatively small in diameter and usually contain a sparse amount of vacuolate protoplasm, which does not obscure the parasite as completely as in species of *Allomyces*, *Rhipidium*, etc.

In spite of these advantages, however, the author has been unable to solve the fundamental problems in relation to the development of *Rozella* which were enumerated in the introduction. While my observations lead me to believe that no true amoeboid plasmodium is present in the non-septigenous species of *Rozella* and that each infection gives rise to a single thallus or sporangium, proof of these beliefs must await cytological study of fixed and stained preparations.

The zoospores of *R. Cladochytrii* come to rest on the host (fig. 9), round up, and within a period of two to five hours put forth a narrow, short germ tube which penetrates the host wall (fig. 9B, 9F). While a large number of rounded-up zoospores may be found on the rhizomycelium, all do not germinate and infect the host. According to my observations, the majority degenerate. The content of germinating spores slowly flows into the host and may become partly or largely obscured, depending on the density and optical heterogeneity of the host protoplasm in the region of infection. The extramatrical, empty zoospore case shrivels up after germination and soon disappears (fig. 9G, 10). Zoospores may occasionally round up and encyst apart from the host in the same manner described by Miss Waterhouse (1940) for a parasite on *Phytophthora*. Such zoospores have never been seen to resume motility or exhibit diploplanetism in *R. Cladochytrii*, but in two instances they developed germ tubes (fig. 9A) which grew to be 8 and 14 μ long and later degenerated.

After entering the tenuous portions of the rhizomycelium, the young parasite may be recognized under favorable circumstances as a denser globular region (fig. 9G, 10) in the rhizomycelium. Even under the best of optical conditions its outline is partly obscured by the host protoplasm and never appears sharp and distinct. No visible antagonism between the two protoplasts has been observed in the initial stages of infection. As the parasite enters, a very slight local agitation of the host protoplasm occurs momentarily, but no streams or circulatory currents are visible. Very shortly after infection, however, the protoplasm appears to become denser around the parasite as if actual accumulation occurs at the region of entry. This appearance, on the other hand, may be due in part to the opacity of the parasite itself. Later, visible effects of the presence of the

flagellate amoeboid zoospore.—Fig. 7. Zoospore at close of motile period.—Fig. 8. Infection of rhizomycelium.—Fig. 9-11. Developmental stages of parasite in rhizomycelium of *N. profusum*.—Fig. 12. Multivacuolate stage of parasite in sporangium of *N. profusum*.—Fig. 13. Later stage in sporangium of *N. elegans*.—Fig. 14. Cleavage (?) of parasite's protoplasm in sporangium of *C. replicatum*. All obstructing extraneous material omitted from drawing.—Fig. 15. Empty shrunken sporangium of *R. Cladochytrii*.—Fig. 16-19. Stages in resting spore development.—Fig. 20, 21. parasite become apparent in the host protoplasm. It becomes more vacuolate and coarsely granular and assumes a faint yellowish gleam. The decrease in degree of dispersion of the granular refractive material is very characteristic and leads to the formation of globular, elongate, and irregular gleaming particles or masses (fig. 11, 12). In the early stages of infection no hypertrophy is visible, and in regions where it occurs it is not noticeable until fifteen to twenty hours after infection.

The parasite appears to lack a definite structural membrane in the early developmental stages (fig. 10-12), but it is doubtless immiscible with the host protoplasm. While I have no direct cytological data to support this view, I question the assertion that the parasite loses its identity, infiltrates the interstices and vacuoles, and mixes with host protoplasm as Fischer and Foust have reported for *R. septigena* and *R. Allomyces*. No amoeboid movement of the young thallus has been observed, although at times it may be elongate and slightly irregular in outline. As the parasite grows and increases in size, numerous small vacuoles appear where it is located in the host (fig. 11, 12) in the manner described by Cornu, Fischer, and Foust for other species of *Rozella*. Fischer in particular speaks of these vacuoles as relating to the host protoplasm, but my observations lead me to believe that they belong to the parasite, as is suggested in figures 11 and 12. The fact that they become fewer in number and larger in size and eventually form a large central vacuole in the mature sporangium of the parasite supports this view. Granules and globular masses of various sizes and shapes are usually present in the large vacuoles and undergo active Brownian movement, as Fischer and Foust have described in *R. septigena* and *R. Allomyces*. In the latter species, however, Foust described them as clumps of host protoplasm undergoing digestion in the vacuoles. In the mature stages of *R. Cladochytrii*, these granules and masses often have the appearance of extraneous food material which has been extruded into the central vacuole before sporogenesis.

The successive developmental phases of the parasite are difficult to follow in sporangia of cladocytriaceous hosts because they are usually obscured in the early stages by the surrounding protoplasm. Infection may occur before or after the sporangia are delimited by cross septa, but usually before they are full grown and mature. The presence of the parasite in older sporangia apparently does not arrest development at once, because normal and fully developed opercula (fig. 1F, 12, 14) have frequently been found on infected sporangia. Parasitized sporangia may be readily distinguished from normal ones and are easily recognized by their vacuolate, dense, coarsely-granular, gleaming contents. Here it is even more difficult to determine which part or if all of the protoplasm relates to the parasite. As the latter matures, however, it fills the sporangium completely and apparently develops a distinct wall which, nonetheless, is impossible to distinguish clearly from that

of the host. In intercalary swellings of the rhizomycelium, on the other hand, the wall appears distinctly at the ends of the oval and elongate thalli (fig. 1A-C). Before, during, or after the wall is formed, the small vacuoles fuse into one or two larger central ones (fig. 1C, 14), while the remainder of the protoplasm, apart from the large granules and bodies, becomes more finely and evenly granular in appearance. The large vacuoles so formed may be uneven in outline and undergo changes in shape and position.

By this time the exit papillae have been formed. Usually only one is present, but as many as three have been found on one sporangium. In sporangia of *Nowakowskiella*, they push off the operculum if one is present and project out of the short neck (fig. 1F, 13, 14). In size, the papillae vary from 2 to 3.5 μ across and 3 to 5 μ high. They are hyaline and optically homogeneous in contrast to the granular protoplasm in the sporangia. Cleavage of the protoplasm into zoospores appears to be progressive and largely centrifugal instead of simultaneous as reported by Fischer for *R. septigena*. In large sporangia the early stages of segmentation are difficult to interpret, but in smaller ones the scalloped border of the central vacuole suggests the presence of cleavage furrows. Figure 15 shows a small infected sporangium of *C. replicatum*, drawn in median section with all of the obscuring material omitted, in which sharp furrows appear to be developing from the border of the central vacuole. Presumably, as these furrows reach and cut through the plasma membrane, the fluid from central vacuole becomes dispersed among the cleavage segments, because the vacuolar region becomes indistinct and the whole mass of segments shrinks slightly. Later, the central vacuolar space becomes more clearly outlined again and remains after cleavage and the formation of the zoospores have been completed (fig. 1F). The hyaline area or fluid continuous with the exit papilla may extend for some distance down into the sporangium and has a distinct convex boundary where it impinges upon the zoospores, as is shown in figure 1F.

Within twenty to fifty-five minutes after cleavage has been completed, the zoospores begin to glide upon each other and upon the extraneous granules or bodies dispersed among them. This movement increases gradually in velocity, until the whole mass of zoospores is swirling in the sporangium. In a few sporangia in *N. profusum*, however, no movement prior to the escape of the zoospores has been observed, but such cases may be unusual. In dehiscence of the sporangia the exit papillae deliquesce slowly, and the hyaline, slimy fluid flows out and spreads in the surrounding water. In one-half to three minutes the zoospores begin to emerge in a thick stream (fig. 1G), which may run out to a distance of several hundred microns before the zoospores become motile. They are surrounded by the slimy substance which exudes with them from the sporangium. The zoospores lie quiescent for a few seconds, and as the slimy fluid becomes diluted, they jerk about a few times and soon thereafter go darting off. The remain-

ing spores in the sporangium swarm about until they reach the orifice and emerge by their own motility. If unable to escape, they remain active for twenty-eight hours before degenerating. Complete emergence of all zoospores in unobstructed sporangia may last from five minutes to three hours, depending on the size of the sporangium and the ease with which the spores reach the orifice.

A considerable amount of extraneous waste material in the form of granules, globular bodies, and slime remains in the sporangium after all zoospores have emerged. This material is undoubtedly of the same nature as that visible earlier in the large central vacuole. Within a few weeks the empty sporangium may begin to shrink and shrivel, and in such cases the separate wall of the parasite may become more evident. This is particularly clear in the case of intercalary sporangia of the type shown in figure 16.

Zoospores.—The zoospores of *R. Cladochytrii* are characteristic in size, shape, and behavior and may be readily recognized in a mixed culture of chytrid zoospores. As is shown in figures 1G, 2, and 3, they are obclavate and obpyriform as they emerge from the sporangium. The tapering anterior and rounded or slightly flattened posterior ends are strikingly characteristic. Bi- and multiflagellate zoospores are not uncommon (fig. 4-6), but more than 98 per cent of the zoospores are posteriorly uniflagellate. Internally, they appear optically homogeneous except for a region in the center or slightly toward the anterior end which is occupied by several minute globules or granules. This region is not markedly refringent, but it may be readily recognized as the zoospores dart about. No zoospores with one large refractive globule have been found in *R. Cladochytrii*. The motion of the spores in swimming is jerky and darting. The zoospores may stop, suddenly reverse, and start off in another direction. They may continue swimming for one-half to two hours, and as their activity diminishes, they become more globular and look like rain drops (fig. 7). Furthermore, they become vacuolate and increase slightly in size, so that if an accurate picture of their characteristic shape and size is desired, they must be studied shortly after emerging from the sporangium.

Resting spores.—The resting spores of *R. Cladochytrii* were found in abundance in *C. replicatum* and *N. profusum*; sparsely in the other hosts. They usually appear at the conclusion of the zoosporic phase and as the culture becomes old, but zoosporangia and resting spores may sometimes be found together. The development of the spores is fundamentally similar to that described by Cornu, Fischer, Butler, and Foust for other species of *Rozella*, and nothing significantly different has been observed. Successive developmental stages are shown in figures 17 to 20. The early stages may be readily recognized by the density of the protoplasm in the center of an infected sporangium or intercalary enlargement. Later the protoplasm becomes sparse at the periphery as it accumulates around the parasite (fig. 17), so that more or less radial strands become evi-

dent. No sharply-defined membrane around the parasite is visible at this stage, but later (fig. 18) the wall may be easily seen. When viewed from above and *in toto*, the host protoplasm appears to impinge directly on the developing resting spore, but in median views it is obvious that a hyaline zone separates the host and pathogen. Such a zone or areola appears to be a constant character of spore development in *Rozella* and has been reported by all students of this genus. It is usually surrounded by a dense layer of host protoplasm from which run numerous radial streams to the periphery. It is in this hyaline zone that the echinulations on the exospore appear, which suggests that it is the region of transformation of the host protoplasm into spore wall material. In *R. Allomyces*, however, Foust reported the granules migrate bodily into this zone, arrange themselves "at right angles to the spore wall, and appear to fuse forming spines." No fusion of granules has been found in our material, but the spines and excrescences, nevertheless, appear to be formed from modified host protoplasm.

The resting spore of *R. Cladochytrii* may be smooth (fig. 22), warty (fig. 21, 24), or spiny (fig. 20, 23, 25). The spines may be long and sparse (up to $3.5\ \mu$) or numerous and shorter. A few spores have been found (fig. 24) in which spines are interspersed among warts or excrescences. A smooth wall usually indicates immaturity, but in *R. Cladochytrii* smooth spores may attain maturity and germinate without the formation of spines or warts. The wall is relatively thin, $1.5-2\ \mu$, and hyaline or faintly amber in color. The spores are predominantly spherical in shape, but oval and slightly elongate ones may also occur. They also vary considerably in size; ranging from $10-14\ \mu$ in diameter in *C. replicatum*, $13-15\ \mu$ in *C. hyalinum*, $9-13\ \mu$ in *C. crassum*, $8-22\ \mu$ in *N. profusum*, $12-16\ \mu$ in *N. elegans*, and $11-15\ \mu$ in *N. ramosum*. The protoplasm of mature spores is coarsely but more or less evenly granular with a large, slightly irregular vacuole in the center. This clear central region has been described by other workers as a large globule of hyaline substance, but in our species it appears to be vacuolate.

Germination may begin within six weeks after the resting spores are formed. By this time the host cell has partially degenerated and freed the spores, but the latter may germinate while the host sporangium is still intact. In this process they are transformed directly into zoosporangia and produce posteriorly uniflagellate zoospores in the manner described by Foust for *R. Allomyces*. While smooth and spiny resting spores have often been found associated with and were generally believed to relate to *Rozella* parasites, Foust was the first to observe their germination and thus prove conclusively their direct relationship. The initial germination stages are difficult to detect in *R. Cladochytrii*, but in the process the protoplasm becomes more finely granular and the central vacuolate region less distinct in outline. A pore is soon formed from which an exit papilla projects to the outside. The latter may be

low and inconspicuous (fig. 23) or fairly high and tapering (fig. 24). The protoplasm cleaves into segments (fig. 23) which eventually begin to glide upon each other and move slowly about. Shortly before the exit papilla deliquesces, the movement becomes increasingly rapid, until the entire mass is swirling about. This whirling motion and subsequent stages of zoospore behavior are similar to those described previously for the zoosporangia. As the exit papilla deliquesces, a mass of slime exudes and spreads in the surrounding water, and in a short while the zoospores emerge. These likewise lie quiescent for a few seconds in the slimy material, jerk about a few times, and then dart away. The zoospores from germinating resting spores are similar in appearance, behavior, size, and structure to those from the evanescent zoosporangia. They have been observed coming to rest on incipient sporangia and intercalary swellings of the host and starting new infections. It is accordingly obvious that the resting spores described above are a part of the developmental cycle of *R. Cladochytrii*. Within a few days or weeks after germination, empty resting spores collapse and shrink.

ROZELLA ENDOCHYTRII.—This species parasitizes the sporangia of *Endochytrium operculatum* but does not cause hypertrophy or septation of the host. It was collected in April, 1941, from a water trough on the Karling estate near Austin, Texas, and has been kept in culture on its host at Columbia University up to the present time. It differs from *R. Cladochytrii* primarily in the shape, structure, and appearance of its zoospores, and secondarily because it does not cause hypertrophy and appears to be limited to a single host. Extensive inoculation experiments involving the same fungi used in studying *R. Cladochytrii* have been made, but all results obtained were negative. In this connection it may be further noted that in the oat leaves which harbored the parasitized sporangia of *E. operculatum* were numerous thalli and sporangia of *Rhizophlyctis petersenii*, but all of the latter were healthy and uninfected. In some portions of the leaves the infected sporangia of *E. operculatum* were almost surrounded by thalli of *R. petersenii*, thus affording ample opportunity for infection, but none of the latter thalli were attacked.

Because of the large size of the host sporangia, it has been impossible to follow the developmental phase of the parasite. Accordingly, less is known about this species than *R. Cladochytrii*. Infection of

young incipient sporangia has been seen but rarely (fig. 26), which may be partly due to the intramatrix habit of its host. In one instance a rounded zoospore was found attached to the main rhizoidal branch of *E. operculatum*, but germination and infection did not occur. Although it is possible that the zoospores may infect the rhizoids also, I have never found sporangia of the parasite in these organs. Since the host is an intramatrical saprophyte, it is difficult to conceive how the zoospores of *R. Endochytrii* get to it, unless they are capable of penetrating the substratum or unless parts of the host are directly exposed. Infected sporangia of *E. operculatum* have been found only in substrata which were decayed and undergoing degeneration. Under such conditions, *E. operculatum* may often be partially extramatrical and thus vulnerable to attack. Infection apparently occurs most abundantly when the host is young, but the fact that parasitized sporangia with long exit canals (fig. 29, 30) and fully developed opercula frequently occur suggests that full-grown sporangia also may be attacked. On the other hand, it is equally probable that the presence of the parasite does not inhibit development in the early stages of infection, so that the parasitized sporangium may often reach full development.

The symptoms of the disease and the internal appearance of infected sporangia are strikingly similar to those described in relation to *R. Cladochytrii*. As the parasite develops, the protoplasm becomes vacuolate, coarsely granular, with numerous irregular and globular bodies, and assumes the characteristic gleaming appearance (fig. 2). Further development involves fusion of the smaller vacuoles into one or two large central ones (fig. 28) and the accumulation of granular material in the center. The scalloped border of the central vacuole shown in figure 28 suggests that progressive cleavage has already begun, although the exit papilla is not evident. The latter may push through the wall of the host or use the opercular openings. In the latter event the operculum, if present, is pushed up (fig. 29), and the exit papilla projects out as a hyaline, dome-shaped plug. These may vary from one to four in number, and from 2 to 6 μ in height. The wall of the infected sporangium usually seems considerably thicker than that of healthy ones, which may be due to the addition of the parasite's surrounding membrane. Cleavage and delimitation of the zoospores appear to be the same as in *R. Cladochytrii*, although it has been impossible to follow the successive steps. Within sev-

Sporangium filled with slimy substance and extraneous bodies left behind by the parasite.—Fig. 36-47. *Rozella Rhizophlyctii*.—Fig. 36. Pyriform zoospore with a small globule and long posterior flagellum.—Fig. 37, 38. Amoeboid stages of same.—Fig. 39, 40. Bi- and triflagellate zoospores.—Fig. 41. Zoospore at close of swimming period.—Fig. 42. Multivacuolate stage of parasite with two exit papillae.—Fig. 43. Later stage with three large vacuoles.—Fig. 44. Parasite at the conclusion of cleavage.—Fig. 45. Emergence of the zoospores. A mass of spores are stuck together at the exit papilla.—Fig. 46. Mature resting spore.—Fig. 47. Empty resting spore which has apparently germinated.

eral minutes after cleavage has been completed, the zoospores begin to glide upon each other and upon the extraneous bodies among them. As in other species of *Rozella*, this movement increases in intensity until the zoospores are swirling in the sporangium and the exit papillae deliquesce. The deliquescence of the exit papillae, emergence of the zoospores, their initial behavior, and subsequent method of swimming are so similar to those described for *R. Cladochytrii* that it would be superfluous to describe them in detail again.

Their structure and appearance, however, are somewhat different. As is shown in figures 30, 31, and 32, they are usually obclavate to pyriform and sometimes arched. The anterior end tapers slightly, while the posterior is broader and rounded. Internally, they are optically homogeneous except for two and sometimes three denser globular areas. The anterior globule is usually smaller than the posterior one. These regions are not brilliant or particularly refringent, like the globules of most chytrids, but their refractive index is different from the surrounding protoplasm. They may be described as having a dull hyaline gleam, if such contradictory terms may be used. Consequently, when viewed under low magnifications, the darting zoospores give the impression of short rod-shaped, hyaline bacteria with two slightly more refractive endospores. When trapped in the sporangium or a tight place under the cover slip, they may become amoeboid (fig. 33), dragging the flagellum along behind. Most of them are $3.4\text{--}4\ \mu$ long \times $1.5\ \mu$ wide at the middle, and unflagellate, but occasional large bi-, tri-, and tetraflagellate zoospores also occur. Figure 34 shows a large amoeboid segment which possessed five flagella. Zoospores may also round up and encyst (fig. 35) at the edge of water drops and remain in this condition for many hours before degenerating.

The size and shape of the sporangia of *R. Endochytrii* vary according to those of the host cell. Sporangia up to $275\ \mu$ in diameter have been found. Since the zoospores are comparatively minute, the number produced in one sporangium is extremely great. Taking the diameter of an encysted spore (fig. 35) as an index of zoospore volume, the approximate number per sporangium may be computed. In the largest sporangia it obviously runs into the hundred thousands. It is accordingly not uncommon to find the entire mount teeming with darting zoospores when several large sporangia are dehiscing. As in other species of *Rozella*, zoospores which fail to find the exit pore may remain active for many hours before degenerating. Numerous granules, globular bodies, and slimy material are usually left behind in the sporangium (fig. 36) after the zoospores have emerged.

Resting spores have not been found in this species, although it has been kept in culture on its host for several months. Our knowledge of *R. Endochytrii* is accordingly incomplete, but the characteristic structure and appearance of its zoospores, nevertheless, set it apart from the other known members of *Rozella*.

zella. These characters together with the limited host range of the parasite, in my opinion, warrant the designation of this organism as a new species.

ROZELLA RHIZOPHLYCTII.—This species parasitizes the sporangia of *Rhizophlyctis petersenii* and is characterized by broadly pyriform zoospores with a comparatively long flagellum and spiny resting spores. Its host and substratum were collected from a ditch filled with rain water in a cow pasture on the Karling estate near Austin, Texas. This locality is doubtless the source of the parasite also, because no opportunity for contamination was presented in the subsequent handling and culturing of the host.

The shape and structure of the zoospore of this parasite differ from those of other species, and these differences coupled with a limited host range indicate that it is possibly a hitherto unknown member of *Rozella*. I am accordingly diagnosing it as a new species and proposing the name *R. Rhizophlyctii*. It is not improbable, however, that this species may be identical or related to the parasite which Miss Ward found in *Rhizophlyctis rosea*. She found only a few immature resting spores and referred them to an unidentified species of *Rozella*.

ROZELLA Rhizophlyctii *sp. nov.*—Sporangia solitary, filling host cell and conforming with the latter's size and shape, spherical, $20\text{--}110\ \mu$, oval, and irregular with 1 to 4 exit papillae which usually project out of the short necks of the host; wall of sporangium usually indistinguishable from that of the host cell. Zoospores hyaline, broadly pyriform, $2.5\text{--}3\ \mu \times 1.5\text{--}2\ \mu$, tapering slightly at the anterior end, with a minute globule near the posterior end; posteriorly unflagellate, rarely bi- and multiflagellate; flagellum $16\text{--}18\ \mu$ long; swirling in the sporangium before emerging; darting about rapidly in swimming, occasionally becoming amoeboid. Resting spores slightly yellow, oval and spherical, $14\text{--}18\ \mu$ in diam., with a large central vacuole and coarsely granular cytoplasm; wall spiny, $1.8\ \mu$ thick, spines $1.5\text{--}2\ \mu$ long; apparently transformed directly into a zoosporangium in germination and forming zoospores.

Parasitic in *Rhizophlyctis petersenii*, Austin, Texas, without causing apparent hypertrophy or septation of the host cells.

Fungus parasiticus; sporangia solitariis, longitudinem latitudinemque cellae matricialis in toto complentibus, spaeicis, $20\text{--}110\ \mu$, ovalibus, irregularibus, cum 1–4 papillis exeuntibus plerumque ex brevibus collis matricilibus se proicientibus; pariete sporangii ex cella matricali fere non discernendo. Zoosporis hyalinis, late pyriformibus, $2.5\text{--}3 \times 1.5\text{--}2\ \mu$, anteriore ex parte cacuminatis et minutissima gutta densissima in cytoplasmate praeditis; e posteriore unflagellatis, aliquando bi- et multiflagellatis; flagello $16\text{--}18\ \mu$ longo; se in sporangio torquentibus antequam emergunt; natantibus emicatum, raro amoeboides. Sporidis perdurantibus subflavis, ovalibus et sphaericis, $14\text{--}18\ \mu$ diametro, cum maxima gutta centrica et protoplasmate crasse granuloso; pariete spiculoso, spiculis $1.8\ \mu$ diametro et $1.5\text{--}2\ \mu$

longo; directa germinatione, ut videtur, in zoosporangium transformatis ut zoosporae formentur.

This species was believed to relate to a new small-spored species of *Rhizophlyctis* when first observed, but more intense study showed that the thalli at hand were those of *R. petersenii* infected with a foreign organism. As soon as this became evident, infection experiments involving the fungi used previously were made to determine the host range and pathogenicity of *R. Rhizophlyctii*. All attempts to infect other species failed, which indicates that this parasite is limited in host range.

As in the case of *R. Endochytrii*, it is difficult to determine with certainty whether or not this species causes hypertrophy of its host, because the normal host sporangia vary so greatly in size and shape. Although very large and irregular parasitized sporangia have often been found, it is not obvious that this large size is due to the presence of the parasite. The same is true in relation to observed irregularities in shape of infected sporangia. Internally, however, *R. Rhizophlyctii* has a conspicuous effect. The protoplasm of normal, healthy sporangia of *Rhizophlyctis petersenii* is usually salmon pink to light red in color, but in parasitized ones it is hyaline. As in the case of *R. Cladochytrii* on *Cladochytrium replicatum*, pigment formation and development is inhibited by the presence of the parasite. While it is true that in old cultures of *R. petersenii* growing on cellophane, sporangia may become almost hyaline, their appearance in contrast to parasitized ones is nonetheless different and recognizable.

The emergence, initial behavior, and motility of the zoospores of *R. Rhizophlyctii* are fundamentally similar to those of other *Rozella* species. In a few sporangia, however, masses of zoospores have been observed to emerge before they were completely separated. Such masses often remained together at the mouth of the exit papillae and obstructed the opening (fig. 46) or moved away as a unit shortly after emerging. In the former instance the zoospores pulled and twisted about, until the posterior flagellum was freed and stuck out at right angles to the group. Eventually the zoospores disengaged themselves and darted away. The behavior of these zoospores was very similar to that described by Fischer (1882) for *R. septigena*.

The zoospores of *R. Rhizophlyctii* are more broadly pyriform than in the previously described species, while the flagellum is on the average 3 to 4 μ longer. Most of them are uniflagellate, but occasional bi- and multiflagellate zoospores and irregular segments may occur (fig. 40, 41). Each spore includes a minute body which is not very refringent and appears almost back in transmitted light. One to several much smaller granules may also be present in the cytoplasm (fig. 37-40).

The method of infection, entrance of the parasite, appearance of infected sporangia (fig. 43, 44), delimitation, and maturation of the zoospores are much the same as those described for *R. Endochytrii*, so that the details need not be repeated again. Figure

45 shows a noteworthy sporangium in which the parasite apparently does not completely fill the host cell.

Only a few resting spores have been found to date, and all of these were spiny. They develop in the same manner as those of *R. Cladochytrii*, and no fundamental differences in the process have so far been observed. Likewise, their internal structure and appearance are essentially the same. Although no stages in germination and emergence of the zoospores have been seen, these processes are apparently similar to those of *R. Allomyces* and *R. Cladochytrii*. Three empty spores with exit pores were found in an old culture, which suggests that the resting spores of this species also function directly as zoosporangia and form zoospores within.

Discussion.—The three species described in this paper appear to belong in the so-called "sporangium-group" of *Rozella* and have posteriorly uniflagellate zoospores. The addition of these species brings the number of members in this group to twelve or possibly thirteen, while only two certain and two very doubtful species belong in the "septigena-group." The discovery of three additional species with posteriorly uniflagellate motile cells is further proof that *Rozella* is characterized by zoospores of this type instead of biflagellate heterocont ones as Fischer maintained. It is thus obvious, as Sparrow has already pointed out, that *Rozella* should be retained in the original sense of Cornu. In that event, *Pleolpidium* becomes a synonym of *Rozella*. Whether or not Cornu's *R. septigena* and *R. Allomyces* Foust should be included in this genus depends on the interpretation of *Rozella* and remains to be determined from careful cytological studies. If, as is now generally believed, each infection gives rise to a single sporangium in the non-septigenous group, whereas in the "septigena-group" a plasmodium is formed which segments into a number of portions and gives rise to several sporangia, these differences in type of development may be significant enough to justify the creation of a new genus for the septigenous species. Conclusive evidence of such differences has not yet been presented, and it is accordingly wiser to retain the two groups within the same genus for the time being.

Pleolpidium inflatum Butler and the parasite described by Miss Waterhouse in *Phytophthora*, however, cannot be included in *Rozella*, because both species have biflagellate zoospores. Otherwise they appear to resemble *Rozella* species of the "sporangium-group," although they are not yet fully known. No septation of the hypertrophied host cells is produced, and each infection seems to give rise to a single sporangium. The structure of the zoospores, nevertheless, excludes these species from *Rozella*, and it is obvious that they should be placed in a separate genus. Since they do not fit into any of the known genera which are characterized by zoospores of this type, a new genus, *Rozellopsis*, is proposed for these species.

The disposition of Fischer's biflagellate, heterocont *R. septigena* and *R. simulans*, however, remains unsettled. Fischer claimed that his *R. septigena* is the same as Cornu's species but occurs only on species of *Saprolegnia*, while *R. simulans* is limited to *Achlya*. The species are otherwise alike. It is not improbable that Fischer may have been incorrect about the number, place of insertion, and relative lengths of the flagella in *R. septigena* Cornu, or he may have attached too much significance to the occasional large, abnormal biflagellate zoospores and regarded them as typical of this species. Such zoospores were previously observed by Cornu and later by Sorokin (1883), but they regarded them as abnormal. On the other hand, it is equally probable that Fischer actually had at hand a *Saprolegnia*-inhabiting, septigenous species with biflagellate, heterocont zoospore which he took to be Cornu's *R. septigena*. Tokunaga's confirmation of biflagellate zoospores in *R. simulans* supports the probability of the existence of septigenous species with zoospores of this type. It is also not improbable that Fischer's *R. septigena* and *R. simulans* may be identical or that the latter species is a physiological variety of the former. Subsequent workers have accepted Fischer's inoculation results without much question. Maurizio (1895), Minden, and Tokunaga subsequently reported this species in *Achlya* sp., *A. racemosa*, and *A. flagellata* from Switzerland, Germany, Italy, and Japan, respectively, but none of them tested its pathogenicity to species of *Saprolegnia*. The resting spores which Minden figured in the short hypertrophied side branches of *A. racemosa* are strikingly similar to those of *R. septigena*, which further suggests that the two species may be identical or closely related. However, until further studies have been made, their identity and relationship will remain doubtful.

Whether or not *R. septigena* Fischer and *R. simulans* may be included with Butler's and Miss Waterhouse's species in the new genus *Rozellopsis* is not

certain, because resting spores have not been observed in the latter two species. In the interests of clarity and convenience, however, it may be worth while to include them in this genus for the time being. *Rozellopsis* accordingly becomes a parallel genus with *Rozella* by including both "sporangium" and "septigenous" biflagellate, heterocont species. Under this interpretation, *Rozellopsis* includes four species: *R. inflatum* (Butler) comb. nov., *R. waterhousei* sp. nov., *R. septigena* (Fischer) comb. nov., and *R. simulans* (Fischer) comb. nov.

SUMMARY

Parasitism among chytrids appears to be comparatively rare; only nine cases have been reported up to the present time. Of the nine species known, none attacks hosts which belong to the same genus as the parasite, and only one occurs on a host of the same family. Five of the nine parasites belong to the genus *Rozella* and cause marked local hypertrophy or septation of the host cell, or both.

Infection experiments show that *R. Cladochytrii* is ubiquitous in host range. It parasitizes three species each of *Cladochytrium* and *Nowakowskiella*, but does not attack monocentric rhizidaceous chytrids or filamentous Oomycetes. *Rozella Endochytrii* and *R. Rhizophlyctis* sp. nov. appear to be limited to *Endochytrium operculatum* and *Rhizophlyctis petersenii*, respectively.

The results of this study show that the zoospores of *Rozella* are predominantly posteriorly uniflagellate and thus support the view that this genus should be retained in the original sense of Cornu. *Pleolpidium* is accordingly reduced to the status of a synonym of *Rozella*, and a new genus, *Rozellopsis*, is proposed for the biflagellate, heterocont, *Rozella*-like species reported previously in the literature.

A CYTOLOGICAL STUDY OF THE CAROTENE IN THE ROOT OF DAUCUS CAROTA UNDER VARIOUS EXPERIMENTAL TREATMENTS¹

T. E. Weier

SO FAR AS I am aware, Arthur Meyer's description (1883) of the carotene bodies in the carrot root is still the most complete and detailed report on the subject. In cells close to the cambium he describes very small reddish bodies which enclose starch grains. Farther from the cambium these bodies and the enclosed starch grains enlarge, the bodies still maintaining their reddish or orange color. Eventually the starch is dissolved. In cells containing but very little starch he found either: (1) small yellowish granules which are recognized as starch-free leucoplasts, or (2) many such leucoplasts grouped together in one large mass, or (3) thin-walled vesicles which can be interpreted as having originated through the dissolution of the enlarged starch grains, or (4) many characteristic tubes and needles of carotene. In the outer portions of healthy and older carrots he found very many well-formed rectangular or rhomboidal bodies. Meyer also noted rows of several starch grains enclosed in a narrow ribbon of carotene and other cases in which only a single starch grain was embedded in the pigment. In some instances only a portion of pigment body was occupied by the starch grain, while in others the starch grain was attached only at one end of the chromoplast.

Meyer believed, though without a great deal of evidence, that the stroma of the plastid was gradually absorbed as the cells aged. While this process was going on, there occurred an accumulation of the pigment around the starch grain resulting in the formation of a tube of pigment. Finally the starch grain also dissolved, the dissolution being most rapid where it came in contact with the pigment. When the starch had completely disappeared the tube of pigment stretched, forming the typical carotene crystal of the carrot root.

Meyer noted, in addition to these bodies, smaller brownish granules which were clumped together in large masses, and which he interpreted as degradation products of the carotene crystals. Within the xylem region he noted very small reddish and yellowish-green pigmented bodies.

In cold alcohol the crystals of carotene in the outer portion of the older carrots dissolved very slowly. When hot alcohol was used they disappeared rapidly

and left no residue. From this experiment Meyer concluded that the pigment bodies were composed of pure pigment not containing any stroma or *Farbstoffträger*. Further experiments led him to believe that the rods and plates of pigment were pure carotene. He believed that, as long as the pigment was in young active cells, it was associated with a cytoplasmic stroma. In older cells this cytoplasmic material was withdrawn. So long as the carotene is mixed with other substances, the crystallization force results in tubes and spirals; later, when the carotene becomes entirely free from associated material, real crystals are formed.

Guilliermond's (1933) description of the carotene in carrot is somewhat similar. He believes that the carotene and starch form within mitochondria, that the starch is resorbed, and that sometime before the pigment becomes pure and crystalline the mitochondrial substrate is withdrawn, leaving the crystal of carotene free in the cytoplasm.

According to Strain (1938) the leaf xanthophylls are quite probably associated with cellular proteins and lipoids. The evidence for this is based upon the relative absorption properties of the pigments in living cells and in test tubes, the action of heat and enzymes on leaves, the extraction and separation of the pigments in green and etiolated leaves, and the reactive properties of the pigments in combination within the cell and of these same pigments after the combination has been disrupted by the action of chemical reagents, enzymes or heat.

The present study reports on the microscopic appearance of the carotene in the cells of the carrot root. The pigment is present in discrete crystal-like bodies, associated with starch grains in a complex, resembling plastids, and in irregular small patches of cytoplasm. The behavior of the pigment following changes in the cytoplasm, such as liquefaction, coagulation and desiccation, is dependent upon its association with the cytoplasm.

METHODS.—Field grown carrots were used exclusively. These were grown in the field throughout the year in Davis. While this assured a constant supply, it introduced a seasonal variation in carotene and starch content which, when combined with possible varietal differences, introduced factors which cannot

be successfully studied by cytological techniques alone.

Carotene is easily destroyed within the cells. The usual cytological techniques either dissolve or decompose it. It is preserved quite well by weak osmic acid and may be observed in good condition in living cells,

for which reason free-hand sections were used exclusively in this study. This treatment, obviously, does not permit of a thorough investigation of all cytoplasmic structures within the cell, nor of the development of the carotene and of other bodies in the meristematic cells.

Free-hand sections made from freshly gathered carrots were examined in M/40 phosphate buffers with a pH of 7.0. No observations were carried out on sections for longer than four hours. During this time cyclosis was active, and no signs of cellular degeneration in uninjured cells were apparent.

The solvent action of pyridene, various strengths of ethyl alcohol, methyl alcohol, petroleum ether, chloroform, the action of sodium oleate, of formaldehyde, of phenol and HCN were observed directly on the living material. The free-hand sections were first mounted in the phosphate buffer, the cytoplasmic activity noted and the reagent drawn under the cover glass. Its action was then observed. The effects of heat and of desiccation on the cytoplasm and pigment were studied by drying the sections at temperatures ranging from 4°C. to over 200°C.

Observations were carried out in both direct and dark field illumination. In direct light Zeiss apochromatic objectives 120×, N. A. 1.3 and 90× N. A. 1.3 were used; for dark field work the 60× N. A. 1.0 apochromatic objective supplied with a diaphragm was used; the dark background was supplied by a Zeiss cardioid condenser.

THE MACROSCOPIC REGIONS OF THE CARROT ROOT.²
—The ontogeny and structure of the fleshy storage organ (root and hypocotyl) of *Daucus carota* have been recently considered by Esau (1940). The following description of the macroscopic structure of the carrot root utilizes the information contained in the above reference and adds some new observations on fresh sections.

The central portion of the root, the core, is composed of the xylem; the peripheral portion is mostly phloem. A narrow layer of pericycle and periderm cells occurs on the periphery of the phloem. Both the xylem and the phloem are highly parenchymatous and are separated from each other by a narrow translucent band of cells, the cambium.

In fresh sections of the carrot root, translucent and opaque areas are combined into a characteristic pattern. The major opacities are formed by several structures, the rays, the parenchyma accompanying the secondary roots, and by the secretory tissue. The rays and the secondary roots form the radiating sheets of tissue, and the oil ducts with their secretory cells appear in concentric layers crossing the rays. The opacity of these regions results from the presence of numerous large intercellular spaces. The parenchyma of the pericycle and of the vertical system of the xylem and phloem is comparatively compact and appears translucent. The vessels and the sieve tubes are imbedded in the translucent areas, although the vessels themselves are recognizable as very small opaque spots. The opaque rays in the phloem extend almost to the periphery of the organ and give an indication of the amount of tissue contributed by the phloem. The narrow layer beyond the rays is composed of pericyclic cells and of periderm of pericyclic origin.

² The writer acknowledges the assistance of K. Esau in the preparation of this part.

THE MICROSCOPIC APPEARANCE OF THE CAROTENE. —Carotene in cells differentiating from cambium.—

The greatest concentration of the carotene occurs in the parenchyma cells of the phloem and the pericycle. There is no visible difference between the carotene content of the opaque rays or of the more translucent areas described above. Both regions seem to have the same amounts and types of carotene crystals. A much smaller amount of pigment forms in the xylem. Its formation here seems to be generally more rapid than in the phloem. Xylem cells close to cambium contain large numbers of small bodies of carotene, while in the phloem well-developed carotene crystals appear usually only in the more mature tissue. This condition renders the phloem and pericycle more favorable for the study of the pigment and the great majority of the observations were carried out in these tissues.

In differentiating cells of carrots collected during the summer months, the pigment appears in two forms: as definite small crystals and as an amorphous mass tingeing the cytoplasm.

Relatively large clumps of cytoplasm are frequently observed to have a yellowish tinge. While it seems reasonable to assume that this color is due to carotene, it is well to bear in mind that a delicate shade of yellow in the cytoplasm is the only evidence. Treatment with sulphuric acid destroys the cell without giving any direct evidence one way or the other. Such patches of cytoplasm tinged with color have been noted many times, both in cells exhibiting active cyclosis and in those devoid of it.

A portion of one cell with actively streaming cytoplasm is shown in figure 1. The relatively large mass of cytoplasm around the nucleus was colored. Stationary granules (a) were noted close to the nucleus, while along the periphery of the tinged mass of cytoplasm the rapidly streaming, colorless cytoplasm carried other granules (b). There was, in addition, a slow movement of granules in a colorless channel (c) through the tinged cytoplasm.

A similar situation was observed in an adjacent cell. Granules moving in the cytoplasmic strand along the periphery of a stationary tinged mass of cytoplasm were shunted aside to become enmeshed in the motionless cytoplasm. Small crystals were also present. The tinged mass of cytoplasm gradually changed shape, the small crystals and granules constantly assuming new positions with reference to each other. In doing so they moved slowly through the colored mass of cytoplasm.

In another cell showing active cyclosis the tinged motionless mass of cytoplasm was confined to one end of the cell. The strand, moving rapidly along one edge of this mass, gradually eroded it away.

Occasionally one obtains a good three dimensional view in which the side wall of the cell is at a slight angle with the rays of light passing through the preparation. In one such case the cytoplasm adjacent to this wall appeared as a gently rolling field. Much of it was colorless, but one region containing

Fig. 5-11.—Fig. 5. Various types of crystals (a) found in an old phloem cell; no starch present.—Fig. 6. Carotene crystals (a) and starch grains (s) in a phloem cell.—Fig. 7. Upon drying, the pigment (a) forms yellowish droplets around the periphery of the cell.—Fig. 8. A large flake of carotene in older phloem cell.—Fig. 9 and 10. Carotene (a) associated with starch grains (s).—Fig. 11. Large clump of starch grains (s) associated with carotene (a).

several small starch grains was lightly tinged with pigment.

Color was never observed in the streaming strands, even when yellowish motionless masses were being eroded away by rapidly moving strands. This is

probably the case because the pigment is so dilute in the strands that it cannot be observed.

Reports of cytoplasm tinged with chlorophyll persist in the literature. They were especially frequent in the older literature. Modern conceptions of the na-

ture of the chloroplast have led to the interpretation that the presence of colored cytoplasm in the cell was due to injury (Weier, 1938). Bold (1940) has, however, recently described a situation in living uncut moss sporophytes of such a nature that makes this interpretation impossible. Evidence is accumulating which leads to the conclusion that in certain, probably exceptional circumstances, the leaf pigments may permeate the general cytoplasm of the cell.

The pigment also occurs in differentiating cells as small crystals similar in appearance to those found in the mature cells. They do not appear to be associated with any specialized region of cytoplasm. In dark field illumination they are brilliantly red, blue and green. This color is not due to fluorescence, as it disappears when the sections are illuminated with those wave lengths of light which are absorbed by the carotene. The small crystals may be traced down to minute points of light and seem to grade down to the limit of visibility. The larger bodies are distinctly carotene crystals. There is some question as to whether the smaller ones are. They resemble the larger bodies in their defraction of the oblique light of the dark field illuminator, in their solubility in alcohol and in their brilliant double refraction between crossed nicols. However, in direct illumination there is no suggestion that the small particles of pigment grade down to the limit of visibility, although such small bodies of carotene might be present, yet quite invisible, with direct illumination.

All of these bodies with intense dark field illumination have a clear outline of light surrounding them. Beck (1938) describes this phenomenon and points out that it is generally caused by the first and most brilliant diffraction ring in the image of each point of the object. It is not to be interpreted as a structural part of the object but is due entirely to diffraction.

In direct illumination the number of different shapes assumed by the pigment in differentiating cells is very large. Figure 4 shows a series of such bodies in the order in which they appeared from the cambium to the first vessel. In the phloem such a seriation would be derived from many more cells. In these xylem cells there are several irregular faintly tinged (d, g, l) masses of cytoplasm, small needle-shaped bodies (e, h), flakes (a, k), ribbons (j), and a spiral (m). None of them gave any evidence of being associated with a specialized mass of cytoplasm.

In osmic acid preparations the carotene bodies are visible in both direct and dark field illumination. Although definitely embedded in the cytoplasm, no differentiated mass of cytoplasm was observed to be associated with them. In some cases blackened granules were in contact with the pigment bodies. Since both pigment crystals and granules are present in the rapidly streaming cytoplasm, a certain number of such contacts should be expected.

While I have emphasized the apparent lack of association of the pigment bodies with any organized cytoplasm or plastid, conclusive evidence has not

been obtained that these carotene bodies did not originate in association with some plastid substance.

Carotene in the cells of the phloem and pericycle.—The development of the carotene crystals in the phloem and pericycle is puzzling, and only a brief description of the appearance of the pigment in the various cells will be given, without any attempt to outline the steps in the formation of the spirals and needles found in the older cells. There are two technical difficulties which make for this confusion. First, a clear-cut seriation of events is lacking. Many types of pigment bodies are found in the same cell, although there may be general differences in the numbers and types of bodies in different regions of the root. Secondly, field grown carrots of different varieties and sizes collected at different times of the year vary in starch and carotene content.

The young carrots examined in the laboratory usually contained but little starch, while the carotene was present in a confusing array of forms. Older, though still immature, field grown carrots examined during the summer months presented the simplest picture. In these carrots three regions outside of the cambium may be distinguished by their starch and pigment content. The first, a differentiating region, is composed of cells which contain little starch and pigment. The second region comprises a varying extent of mature cells containing numerous large starch grains and considerable pigment. The plastid component associated with the starch grains has been stretched so as to be invisible either in living or fixed and stained sections. These grains are usually clumped together (fig. 11). In cells showing active cytoplasmic streaming they move in the cytoplasmic strands. Sometimes the starch grains of a given clump will separate from each other; at other times two or more clumps will join to form a single large mass. Single starch grains may leave the larger clump to move around the cell alone. In the few instances in which observation was continued until movement ceased, the starch grains came to rest in that region of the cell receiving the least amount of light.

The pigment may be present in these cells either as isolated well-formed crystals (fig. 6 and 8), or it may be associated with clumps of starch grains (fig. 9, 10, and 11). In the latter case the whole mass of starch grains (or various portions of the mass) is orange in color. The darker regions (a) in figures 9, 10, and 11 are pigment. This effect may be brought about either by crystals or by carotene in close association with starch. The starch grains are transparent and refract light passing through them, so that crystals tightly massed with starch grains are not visible as such. They may be detected in cells under conditions of cytoplasmic streaming, active enough to separate the starch grains and to free the crystals from the mass. The association of starch and carotene may be recognized by the presence of the pigment between two or more starch grains (fig. 9a and 10a), by its location on starch grains or by the failure of crystals to appear when masses of

starch grains revolve or separate without disclosing crystals. In many cells not showing cyclosis it is impossible to decide whether or not the coloring of the starch mass is due to crystals of carotene or to the association of the pigment with the starch grains.

The third region is differentiated by the lack of starch (fig. 5). It is probably composed mostly of pericycle cells with some of the older phloem cells. This region may constitute the outer half of the carrot, although it usually is much smaller, being confined to from twenty to a hundred cells just inside of the periderm. The pigment is found in most carrots in two distinct colors, red and orange. The orange usually predominates and some carrots may have only orange crystals. It is also found in many diverse forms. Flakes, needles, spirals, long ribbons, short ribbons, narrow ribbons, and broad ribbons are all to be seen in both colors (fig. 5 and 6). One type of body is particularly interesting. It is a long ribbon (fig. 2a) in which one to several small starch grains (s) are embedded. This seems to be one stage in the dissolution of starch and of the subsequent freeing of the carotene and was so interpreted by Meyer. Lack of intermediate stages does not permit a definite conclusion.

These crystals resemble those of differentiating cells in their appearance in dark field illumination and between crossed nicols.

THE EFFECT OF ETHYL ALCOHOL ON THE CAROTENE IN THE DIFFERENT REGIONS OF THE CARROT ROOT.—*Differentiating cells.*—The small size of the pigment bodies in these cells makes study difficult in this region. Cold alcohol dissolves the pigment slowly; no droplets or other type of body were observed to form. It is not possible to say whether or not residue or stroma is left behind after the pigment has been completely dissolved.

Mature cells containing large amounts of starch.—Alcohols of a dilution up to 60 per cent usually have little effect on the pigment in these cells. However, when stronger alcohol is used, the pigment disappears, and olive green droplets appear within the cells (similar to fig. 7). There is some variation in the reaction of these cells to alcohol. Sometimes many droplets form which are relatively insoluble in alcohol. In other instances few droplets form which may dissolve in alcohol. There seems to be some correlation between the number of droplets formed and the condition of the pigment in the cells. More droplets are formed when the pigment is closely associated with the starch grains than when crystals are present. It is not possible to follow the minute changes that are taking place within the cells as the pigment disappears and the droplets form. It is probable that a lipophaneroze (Beauverie, 1926) occurs: the cytoplasm is broken down by the action of the alcohol, releasing lipoids which are present in sufficient quantity to dissolve all of the pigment present. The lipoid thus released forms droplets in which the pigment dissolves, the solution finally being extruded from the mass of starch grain-cytoplasm-pigment complex. Droplets forming in cells with few or

no crystals are slowly if at all soluble in alcohol. They do disappear after several days, but this is quite as likely to be a chemical disintegration as dissolution. The droplets dissolve instantly in chloroform.

Mature cells devoid of starch.—While I have divided the carrot root into three regions for convenience, it must be borne in mind that these regions are not distinctly segregated, nor do they correspond with the gross morphological regions describe above. In general the translucent redder areas contain fewer starch grains, although this is at best a broad generalization.

Dilute alcohol has little or no effect on the carotene bodies in these older cells. Neither 60 nor 80 per cent alcohol, which induce the formation of droplets in starch-containing cells, have any great effect on the carotene crystals.

Ribbons of carotene were occasionally found to fray out at the ends. Less frequently elongated lines or fibers could be observed within the ribbon. This suggests that the ribbon has a parallel alignment of micelles as has been suggested for the chloroplast (Menke and Koydl, 1939) and is in agreement with the doubly refractive nature of the carotene bodies. These various changes in the appearance of the carotene crystals could not be duplicated at will. They occurred infrequently and unexpectedly during the study.

As already mentioned, the pigment is present in most cells in two colors, red and orange. Since in dilute solutions carotene is orange in color and changes to red abruptly at a relatively high concentration, it was thought at first that the color of the pigment was a function of the dilution of the pigment. The ribbons, flakes, and spirals were supposed to be more dilute, that is associated with some lipoidal material (see below), while the needles, being more crystalline, were thought to be pure pigment and should therefore appear red. While this hypothesis to explain the color differences in the pigment bodies held for a number of observations, carrots were obtained late in the fall which contained pigment bodies of all shapes in all colors. There were red flakes and orange needles. When 95 per cent alcohol is drawn over sections of carrots containing bodies of both colors, the orange colored crystals invariably disappear first. I have observed them dissolve completely in one hour, while three hours later the section still contained numerous red crystals.

In 95 per cent alcohol the carotene bodies dissolve slowly. There was no typical pattern in this dissolution. In some cases it was a simple wearing away of the body; in others the ribbon would become vacuolate, the vacuoles coalescing until all of the pigment had disappeared.

In the case of the ribbons or flakes a small colorless residue remained behind. The following examples are taken from my notes:

1. An elongated flattened needle-shaped body was selected for observation in direct illumination.

- a. Ninety-five per cent alcohol was drawn under the cover slip.
- b. Darker granules, surrounded by a clear space appeared within the pigment. These suggested bordered bits of pine tracheids.
- c. These holes enlarged and coalesced, while the borders of the ribbon remained intact and distinct.
- d. A chain or irregular series of isolated colorless granules remained behind as a residue.

Turning to dark field illumination two other elongated ribbons were watched. Vacuoles did not appear in these bodies; they gradually became smaller and smaller. One (fig. 3) was reduced in size as shown. The small granule remaining as residue was quite indistinguishable from any of the other cytoplasmic granules.

The second body broke up into two granules and a group of several small granules very close together. The two small granules were a delicate green in color and they eventually disappeared. The group of granules coalesced to form one colorless body which did not dissolve in the alcohol.

The action of chloroform on the residue was studied. A large flake of carotene was selected in one of these observations. The pigment was dissolved leaving a small colorless flake which was washed with 95 per cent alcohol for forty-five minutes without further change. Chloroform was then drawn under the slip. The colorless flake dissolved immediately leaving no visible trace.

In another instance two long red needles were observed as the alcohol dissolved away the pigment. Here the residue remaining behind retained approximately the shape of the original crystal. When chloroform was drawn under the cover slip, the residues dissolved immediately.

In one case about one quarter of a needle of carotene dissolved completely soon after the alcohol came in contact with it. The remaining three-quarters did not dissolve, although continually washed with 95 per cent alcohol for some time.

On the other hand needles and other crystal-like bodies usually dissolved completely, leaving no visible residue.

THE EFFECT OF DESICCATION UPON THE CAROTENE.—Strain's observations (1938) of the rate of oxidation of the carotinoid pigments led him to the opinion that they were associated or in actual combination with fats or proteins within the cell. That a residue remains when the crystals of carotene are dissolved in alcohol within the cells of the carrot root is definite evidence that this is the case. It was thought that further information might be obtained on this point through a study of the melting points of the carotene within the cells. Such results were, however, unobtainable as the carotene bodies were transformed into greenish globules of pigment upon simply drying the section.

Fresh sections were dried at 100°C., 30°C., 22°C., and 4°C. In all cases the typical pigment bodies dis-

appeared with the formation of yellowish green droplets (fig. 7). These droplets closely resembled those formed in the starch-containing cells when they were placed in alcohol, except that upon drying the droplets appeared evenly distributed throughout all cells of the root.

Sections were dried in a vacuum over calcium chloride for nineteen hours. Droplets appeared under these conditions resembling those that form when sections are dried in air. While not constituting proof that oxidative changes are not responsible for the disorganization, it would lend evidence for that assumption.

Sections were fixed by placing them in a dilute solution of osmium tetroxide for four days. They were washed and examined. The carotene bodies were well preserved. Drying had no noticeable effect upon them. Sections were heated to a temperature of 205°C., which is considerably above the melting point of pure carotene, without apparently affecting the pigment bodies. The action of the heat on the pigment cannot, of course, be followed directly microscopically. The sections were heated and then mounted on a slide for observation. It is possible that the pigment melted and crystallized again in cooling. However, after osmium fixation, the pigment bodies are not transformed into droplets upon drying or heating the sections.

I think that the most logical explanation of these observations is that a disorganization of the cytoplasmic structure occurs upon drying. Lipoids are thus released which in turn dissolve the carotene. Dr. Strain informs me that there is sufficient fatty material within the carrot root to dissolve all of the pigment present. When the sections are treated with osmic acid, the cellular lipoids and proteins are hardened, and subsequently the release of the lipoids does not take place. Carotene is not blackened by the osmium; this would indicate that lipid material associated with it is probably completely saturated.

Petroleum ether.—The carrot selected for treatment with this reagent contained many crystals of carotene in outer cells, while the cells closer to the cambium were well supplied with masses of starch grains and associated pigment. When petroleum ether is drawn over sections mounted in water, no change takes place even after 45 minutes.

Sections were mounted dry, brought into focus on the microscope stage in the shortest possible time and petroleum ether drawn over the sections. There is immediate and complete disorganization. The crystal-containing cells in the outer phloem resemble those having received heat treatment (fig. 7); most of the crystals have disappeared, only a large number of yellowish droplets being visible within the cell.

Additional evidence that the pigment does not go directly into solution in the petroleum ether, but that lipophanerosis occurs and that the solvent is in some manner associated with the cytoplasm, was obtained in another observation. A rather large irregular mass of yellow cytoplasm in which a large ribbon crystal

was partially embedded was watched for some time. Since the pigment bodies had been observed to leave behind a yellow residue when disintegrating after petroleum ether treatment, the yellow color of this cytoplasm must have been due to the carotene. This yellow pigment gradually disappeared, whether through solution in the petroleum ether or through disintegration it is not possible to say. After the cytoplasmic mass had become quite colorless, the red ribbon of carotene gradually became diffuse and smaller, while the colorless mass of cytoplasm again became yellow. There can be no doubt but that the carotene stains the cytoplasm. The mass of cytoplasm remained colored for about ten minutes. After this time the pigment had been completely washed from this cell. About ninety minutes of continued washing with petroleum ether was required for this change. Other cells still contained both crystals of pigment and yellow droplets.

When chloroform replaced the petroleum ether in the sections, large yellowish masses appeared in the cells containing starch, while many yellowish droplets close to the cell wall were noted in the outer phloem cells. The yellow substance is either insoluble or only slightly so in chloroform.

The action of two crystals of pigment under the influence of petroleum ether was checked. In one case the needle of carotene swelled considerably and the pigment gradually disappeared, this time without the coincident appearance of yellow color within the cell. An irregular colorless mass about the size of swollen crystals remained.

In another cell a ribbon was observed to disappear, leaving in its stead a number of irregular yellow bodies.

Methyl alcohol.—Carotene is not soluble in methyl alcohol. When it is drawn over a section of carrot root, the pigment disappears very slowly with the subsequent formation of yellow droplets. Both yellow and red crystals were present in the cells under observation. No difference in their action toward methyl alcohol was noted.

THE ACTION OF FORMOL, PHENOL, AND HYDROGEN CYANIDE ON CAROTENE.—The action of these three substances on the carotene crystals was studied. Formol was chosen because it coagulates the proteins and probably hardens some of the fatty materials. Commercial formaldehyde as well as a two per cent solution were used. Phenol and HCN both kill by liquefying the cytoplasm, HCN, in addition, inhibiting the oxidative changes which take place upon the death of the cell. The concentration of the phenol was two per cent.

There was no change in the appearance of carotene crystals after three days' immersion in the formols, two per cent phenol, and the HCN. When alcohol was drawn over sections which had been previously treated for twenty-four hours with these solutions, the pigment was found to dissolve rather more slowly than from fresh sections. After treatment with two per cent formol the red crystals were very resistant to the action of alcohol. In the phenol treat-

ed material, alcohol caused the formation of greenish droplets which soon disappeared. Red crystals were noted after the sections had been immersed in alcohol for twenty-four hours. Alcohol brings about the dissolution of the pigment bodies in the HCN treated material only very slowly.

When chloroform was drawn over the treated sections mounted in alcohol, the following results were obtained: in 2 per cent phenol, the crystals disappeared without the formation of any droplets; with HCN, brilliant yellow droplets formed, the intensity of the color probably being due to the inhibition of the oxidative changes which normally occur upon death of the cytoplasm; 1 per cent formol caused the formation of greenish droplets. The reaction is fundamentally one between the cellular constituents and the solvents, for these droplets will form even after the sections have been in alcohol for sufficient time to dissolve out all of the pigment. In some sections containing pigment, colorless globules are first formed, the pigment subsequently passing into solution in them. They form rapidly from various points within the cell and enlarge and coalesce until one large globule fills the cell cavity.

There is considerable difference to be noted here from the action of chloroform and alcohol on fresh sections. In the latter, alcohol induces the formation of droplets only in the starch-containing cells where the carotene is not visible in the form of discrete bodies. When crystals of pigment are present, the alcohol dissolves them gradually without the formation of droplets. Chloroform added to these sections results in the complete dissolution of the pigment, leaving the cell washed clear of any color.

When formol, phenol and HCN treated sections are washed and dried, greenish droplets are apparently formed in all cases. In the formol sections, however, this granular stage did not last very long; the sections became faintly colored throughout and soon lost the pigment. In the phenol treated sections the droplet formation was very slow, as crystals were noted after four days of drying. In HCN the droplets formed readily upon drying; they were yellow and eventually disappeared.

ON THE NATURE OF THE CAROTENE BODIES.—There is some doubt as to whether the carotene bodies should be termed chromoplasts, crystals or neither. The pigment is believed to be present either in a crystalline form or in association with some sort of cytoplasmic matrix, *i.e.*, a plastid. Some of the shapes are distinctly crystalline, particularly the long needles which are so frequently encountered. The curved bodies and the long cone-shaped spirals have no counterpart among true crystals. Meyer (1883) considered the needles to be crystalline, and held that, when the pigment was present in the shape of flakes, ribbons or spirals, it was associated with a cytoplasmic matrix. Guilliermond (1933) considered all of these distinct pigment bodies to be crystals.

Diluted pigment is orange in color. At a higher concentration it turns a deep red. If Meyer's interpretation is correct, the flakes, ribbons, etc., which

he supposed to be associated with cytoplasm, should be orange, while the needles should be deep red. This is not the case, for all types of pigment bodies may be either red or orange. Furthermore, according to both Meyer and Guillaumond, when starch and pigment are associated, a cytoplasmic matrix is still present. Yet I have, not infrequently, observed well-formed needles which are supposed to be pure pigment associated with starch.

There can be no doubt that, when large amounts of starch are present, the association between starch, pigment, and cytoplasm is not similar to that occurring when the pigment bodies predominate. The experiments with alcohol indicate this. The question arises, however, as to whether one is to consider this starch-pigment-cytoplasm complex as a typical plastid. Morphologically it does not resemble a plastid. It may be a mass of plastids or some other specialized grouping or arrangement. It is true that the chromoplasts in other cells, such as those of *Gaillardia* hairs, have an amorphous shape; yet one has no difficulty here in recognizing the essential plastid nature.

The experiments with alcohol have already brought out differences between the reactions of the pigment bodies in the carrot and typical chloroplasts. It seemed worth while to treat the material with other reagents toward which plastids have definite reactions.

Sodium oleate.—When typical plastids are treated with a dilute solution of sodium oleate, very definite and characteristic myelin formations are produced (Weber, 1933). Beauverie (1938) reports a rather typical series of changes in the chromoplasts of *Ranunculus* petals; there is a granulation and a very marked lipophanerosis or segregation of the plastid colloids. Sections of carrot roots were mounted directly in a one per cent solution of sodium oleate. After thirty-five minutes' treatment there was no change in the appearance of the pigment. A few of the long ribbons showed some fraying of the ends. After forty-five minutes the cytoplasm had become distinctly granular, but the pigment bodies showed no change in structure. They were distinctly embedded in the granular cytoplasm which showed no specialization adjacent to the carotene body. After forty-eight hours' immersion in one per cent sodium oleate, almost complete cellular disorganization had occurred without seeming to affect the pigment bodies in any way. They were still present in considerable quantity. No myelin formations were observed.

Pyridene.—When mounted in a saturated aqueous solution of pyridene, chloroplasts swell and become very granular. Sections of carrot root were treated with pyridene, either by mounting them directly in a saturated aqueous solution or by subjecting them to the fumes and then mounting them in water for observation. No change was ever observed in the structure of the pigment bodies.

Dilute alcohol.—This reagent brings about a swelling followed by a granulation or vesiculation and subsequently a coalescence of the plastids within a cell (Liebaldt, 1913). Dilute alcohols have no

effect upon the appearance of the pigment bodies in the carrot root.

Distilled water.—In distilled water plastids imbibe water, swell and finally burst (Liebaldt, 1913). Distilled water does not change the appearance of the pigment bodies in the carrot.

Alcohol.—While the action of concentrated alcohol has already been treated in some detail, it should be mentioned here that the pigment bodies in the carrot root may be completely dissolved without leaving a trace of a plastid substrate, or a small colorless granule soluble in chloroform may remain as a residue. When chloroplasts are treated with strong alcohol the chlorophyll is dissolved away, but the plastid substrate remains behind as a definite body with all of the structures of the living plastid distinctly visible (Heitz, 1936; Weier, 1936).

While further work may bring to light the plastid nature of the carotene bodies in the carrot root it does seem that the evidence so far available indicates that the pigment is not at all times associated with a typical plastid substratum. In differentiating cells it appears to be diffused throughout the cytoplasm. In many cells containing starch it is closely associated with starch grains. In this state the pigment-starch-cytoplasm complex is probably in the nature of a plastid. In older cells it is present in the form of bodies, crystalline in appearance, which have no plastid attributes.

BEARING OF OBSERVATIONS ON THE EXTRACTION OF PIGMENT FOR CHEMICAL STUDIES.—While the observations do give rather strong support to the contention that the carotene pigment of the carrot root is associated with some other compound of a lipoidal nature they also indicate that great care must be taken in extracting the pigment for such studies. In the first place the association between pigment and substrate is not uniform throughout the root, and the same solvent may not necessarily extract identical compounds from different associations. Secondly, the disorganization of the cytoplasm with the resulting release of cytoplasmic lipoids must be considered. In most instances the pigment appears to dissolve in these lipoids upon the disintegration of the cytoplasm. This association is not that existing in the living cell, yet it might well be the one extracted for study.

It would appear from these observations that the best way to release the free carotene bodies would be by the use of substances such as sodium oleate which bring about a liquefaction of the cytoplasm without an accompanying visible change in the structure of the carotene crystal.

SUMMARY

In differentiating cells of the carrot root the pigment appears either as small crystalline bodies or it is diffused throughout the cytoplasm. These cells contain little or no starch.

In older cells containing starch the pigment is present in the cytoplasm surrounding these grains. It is not always crystalline in appearance. When it

is crystalline, it may sometimes be attached to the starch grains, or it may be free to move away from the grains in the streaming cytoplasm. When these cells are treated with alcohol of 85 per cent or greater concentration large numbers of greenish granules appear in them.

In older cells the starch is withdrawn and large numbers of carotene bodies of a great variety of shapes remain. These bodies are brilliantly doubly refractive between crossed nicols; they reflect blue, green and yellow light with dark field illumination. When these cells are treated with alcohols of a concentration of 85 per cent or less there is no dissolution or change in the appearance of the carotene. When they are treated with 95 per cent or absolute alcohol, the carotene crystals may dissolve completely or a colorless residue which is soluble in chloroform may be left behind.

When sections of carrot are dried, the carotene appears to dissolve in the lipoids released from the cytoplasm. Large numbers of greenish droplets are formed. These may disappear upon standing for twenty-four hours or longer. The carotene does not disappear from sections which have been treated with weak osmic acid and dried or heated to 205°C.

Commercial formol, 2 per cent commercial formol, 2 per cent phenol and approximately .1 mol HCN do not induce great changes in the appearance of the pigment crystals. These substances do, however, render the pigment more resistant to alcohol. Chloroform induces the formation of greenish or yellow droplets.

The pigment-starch-cytoplasmic complex in the carrot root does not react to alcohol, pyridene, sodium oleate, and distilled water as does the typical plastid.

There is good evidence in support of the contention that the carotene is associated with some other substance within the cell. However, it seems certain that upon destruction of the cell the pigment goes into solution in cellular lipoids. Therefore great care should be exercised in the analysis of the so-called carotene-simplex. Unless correct precautions are taken the associated compounds may be those derived from the cytoplasm rather than those normally in association with the pigment.

SOMATIC CHROMOSOME COMPLEMENTS IN *BOUTELOUA*¹

Jess L. Fults

CERTAIN SPECIES and biotypes in *Poa* (Brown, 1939; Tinney, 1940), *Paspalum* (Burton, 1940), *Spartina* (Church, 1929a, 1929b and 1940), *Andropogon* (Church, 1929a, 1940), *Agropyron* (Peto, 1930) and other grass genera (Nielsen, 1939) have recently been analyzed cytologically. These investigations have shown that in the above genera, differences between species and between biotypes within species are often correlated with such cytological phenomena as polyploidy, cytomyxis and parthenogenesis. These facts, coupled with the fact that there is much variation in plant form between biotypes of certain species of *Bouteloua*, suggested a study of their chromosome complements to determine whether a similar condition existed in this genus.

An early taxonomic treatment (Griffiths, 1912) of the genus *Bouteloua* described and listed 36 species. The range of the genus is from Ontario and Maine south to the West Indies, the Argentine, and the Galapagos Islands. The center of distribution and the greatest number of species are found in west Texas, southern New Mexico, Arizona and northern Mexico where such species as *Bouteloua rothrockii* Vasey, *B. eriopoda* (Torr.) Torr., *B. aristoides* (H.B.K.) Griseb., *B. barbata* Lag., *B. gracilis* (H.B.K.) Lag. and others often form a dominant part of the vegetation. The species which forms the greatest numerical dominance is undoubtedly the common blue grama (*Bouteloua gracilis*) of the southern, central and northern Great Plains. This species, along with side-oats grama, *B. curtipendula*, has the greatest range of any of the species and these together are typical of the two subdivisions of the genus, the *Chondrosium* and *Atheropogon* sections, respectively.

Since the publication of Griffiths' monograph (1912), Hitchcock (1935) has described the seventeen species occurring in the continental United States. He included five of the species names used by Griffiths within other species. Some of Hitchcock's names were also used by Griffiths but in a more limited sense. Besides these changes, Hitchcock added a brief description of *B. gracilis* var. *stricta* (Vasey) Hitchc. Since the publication of Hitchcock's work, Swallen (1935) has described one new species from California (*Bouteloua annua* Swallen). To these, in

the writer's opinion, should be added one species described by Featherly (1931) from Oklahoma (*Bouteloua pectinata* Featherly). In this report the writer recognizes thirty-three species and one variety based on Griffiths' monograph, and the subsequent work of Hitchcock, Swallen and Featherly.

Of these thirty-three species and one variety, seven species, including six biotypes of blue grama (*B. gracilis*), five of side-oats grama (*B. curtipendula*) and three of hairy grama (*B. hirsuta* Lag.) from numerous seed sources have been studied cytologically. Root tip chromosomes have been observed in one or more biotypes in the following species: *Bouteloua breviseta* Vasey, *B. curtipendula* (Michx.) Torr., *B. eriopoda* (Torr.) Torr., *B. gracilis* (H.B.K.) Lag., *B. hirsuta* Lag., *B. rigidiseta* (Steud.) Hitchc., and *B. rothrockii* Vasey.

The extreme variation in plant type in the widely distributed forms of blue grama and side-oats grama has long been known (Griffiths, 1912). Griffiths acknowledged that the northern plains form of blue grama, which normally produces a rough, bunchy sod, with few culms and abundant basal leaves, is different from the typical southwestern bunch-grass with many culms and culm leaves. However, the fact that both are present in the southwest and that intermediate types occur led Griffiths to the opinion that neither form should be recognized as a distinct variety. Since Hitchcock (1935) did not name or describe these separately, he evidently agreed with Griffiths' interpretation. Hitchcock did concede that *B. gracilis* var. *stricta* (Vasey) Hitchc. is different, and, according to the writer's interpretation of Griffiths (1912), this is typically the tall, robust, strictly bunchy form of the southwest.

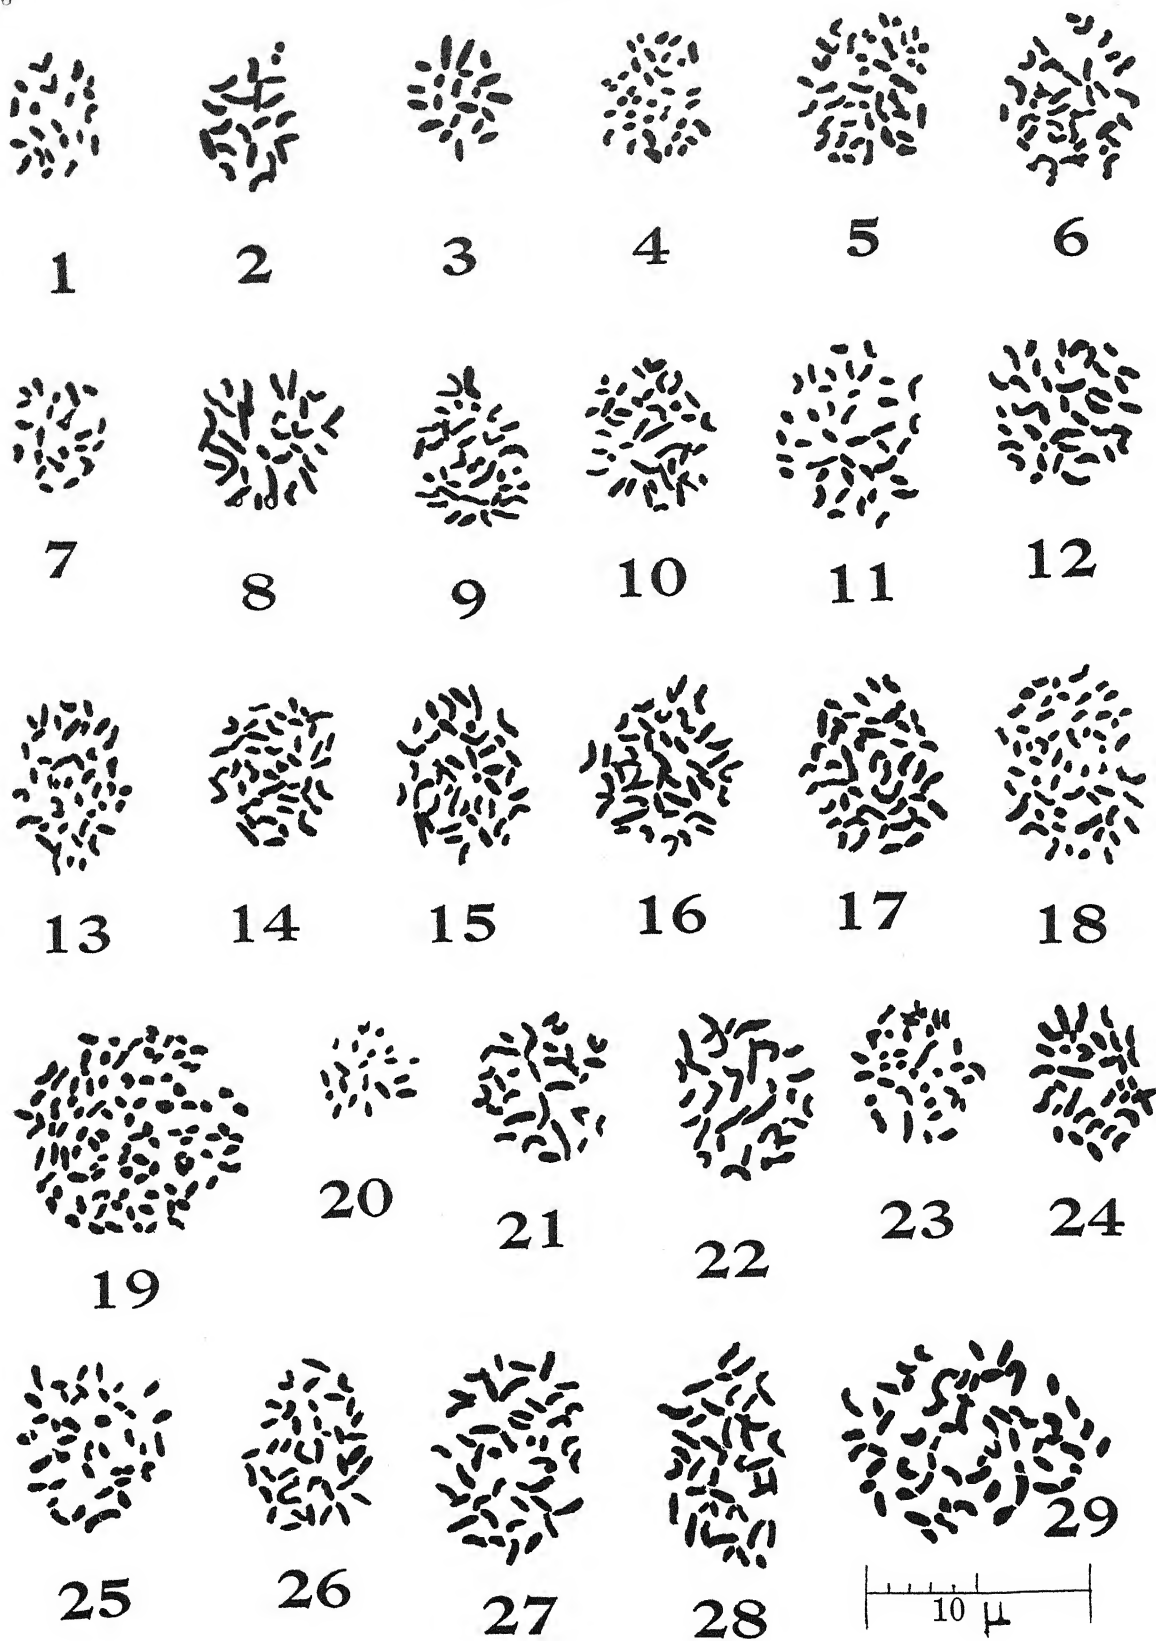

MATERIALS AND METHODS.—The plants used in this investigation were single plant cultures from seed sources ranging from Craigmyle, Alberta, to Iowa, southern Arizona, and New Mexico. One hundred fourteen plants were studied from 85 localities, distributed over every state west of the 100th meridian to the Sierras excepting Idaho, Utah, and Nevada. In *B. breviseta* one plant from one locality was studied; in *B. curtipendula* forty-eight plants representing thirty-eight sources; in *B. eriopoda* five plants from three different areas; in *B. gracilis* fifty-five plants from thirty-eight places of collection; in *B. hirsuta* three plants from three areas; and in *B. rigidiseta* and *B. rothrockii* one plant from one locality each.

All fixations were made with fresh formalin acetic alcohol. The best results were secured by preheating the fixative to 60°C. Root tips killed and fixed on warm bright days gave many more metaphase plates than those taken on cool cloudy days. Little usable material was secured from greenhouse plants growing during the winter months of November through March. The best root tips were obtained during the months of April, May, and early June.

Contribution from the Department of Botany, the University of Nebraska, New Series. No. 131.

The author wishes to express his appreciation for the help and assistance given in pursuing the details of this research to Dr. Elda R. Walker, of the Department of Botany of the University of Nebraska, under whose direction it was begun and concluded. Thanks are also due the Nursery Section, Operations Division, Soil Conservation Service, U. S. Department of Agriculture, for the privilege of using certain habitat photographs and for the plant materials used in this study. Thanks are due the Department of Agronomy, the University of Nebraska, for land and greenhouse facilities, and to the Department of Botany, the University of Nebraska, for certain laboratory privileges and materials.

Repeated efforts to use various modifications of the aceto-carmin smear technique failed to give satisfactory results, because either the chromosomes failed to take enough stain or the cytoplasm stained so darkly that differentiation was difficult. Consequently, the paraffin technique was used. Dehydration was done with the various grades of alcohol, followed by chloroform, chloroform-paraffin, and paraffin. Five or six tips were embedded together and then cut at 12 microns. Staining was done with Heidenhain's haematoxylin that was ripened for a period of two months. Two drops of poleol per 100 cc. of stain were added immediately before use. The addition of this latter compound, an agent for lessening surface tension, greatly increased the penetration and contrast of the haematoxylin.

All drawings were made with the aid of a Bausch and Lomb camera lucida and binocular microscope using $\times 25$ oculars and a $\times 98$ objective. The microphotographs were made with a Model K, Bausch and Lomb camera.

In drawing complements with crowded or overlapping chromosomes, it was often possible to bring all chromosomes into one plane, for drawing and photographing, by gentle pressure on the cover slip with the rounded end of the handle of a dissecting needle. In selecting complements to draw and count, five to ten metaphase plates were examined and the best one used. The one selected was always tested by focusing above and below the plate to make certain complete cells were obtained.

Herbarium specimens of all plants used in the investigation have been deposited in the Herbarium of the University of Nebraska.

OBSERVATIONS.—The morphology of chromosomes has proven to be comparatively uniform (fig. 1 to 29) in all species and biotypes. With few exceptions individual chromosomes were spherical or short to medium length rods with a range in size from 0.25 to 2.00 microns. When complete complements were measured, the predominating types were 0.50 to 0.75 micron long and 0.25 to 0.50 micron wide. In a few, definite V-shaped chromosomes with median spindle attachment were observed. In others what appeared

to be strong attraction between certain chromosomes caused complements to appear to be made up of longer and fewer chromosomes than was actually true. When observed at early anaphase, this bunching of chromosomes was not seen and chromosomes were more nearly the usual length and expected number.

BIOTYPES AND CHROMOSOME COMPLEMENTS IN BLUE GRAMA.—As a result of growing blue grama (*B. gracilis*) from 38 different areas side by side in the same nursery, it was possible to classify them into six biotypes. The two most distinct types corresponded closely with the low northern prairie form and the robust southwestern bunch-grass described by Griffiths (1912). Besides these two, four others, somewhat less distinct, have been observed. All are illustrated in figures 49 to 54 and are described and compared below.

The descriptions of six biotypes of blue grama.—(1) *Oklahoma biotype* (fig. 49) closely related to the Lincoln, Nebraska, salt flats form. *Leaves:* Basal, abundant, very long, lax; few or no culm leaves. Average length of basal leaves 22.19 cm. \pm 0.47 cm.² *Culms:* Mostly short and not overtopping leaves. Average number per plant 115.29 \pm 16.05. *Spikes:* Long, narrow, similar to the New Mexico type. Ascending not spreading. Average length of spikes 35.66 \pm 0.87 mm. *Time of flowering:* Late summer to early fall. *Plant vigor:* Very high.

² These averages were obtained from at least ten measurements on each of twenty different individual plants of the biotype concerned, spaced 2 feet \times 2 feet. The errors shown are standard errors (S.E.) and were calculated by the use of the following formula:

$$S.E. = \frac{S.D.}{\sqrt{N}}$$

S.D. = Standard deviation.

N = Total number in population which is 200 or more in this case.

$$S.D. = \sqrt{\frac{\sum X^2}{N} - \left(\frac{\sum X}{N}\right)^2}$$

Significant differences in any one comparison may be detected by determining whether or not they are at least three times the standard errors of the difference which in turn may be calculated by use of the formula:

$$S.E._d = \sqrt{(S.E._1)^2 + (S.E._2)^2}$$

Where $S.E._1$ and $S.E._2$ are the standard errors of the two averages being compared.

age length, spreading at wide angles to culm. Average spike length 30.87 ± 0.48 mm. *Time of flowering*: Mid and late summer, often with two crops of spikes. *Plant vigor*: Average vigor.

(3) *Nebraska biotype* (fig. 51) most closely related to the Wyoming type. *Leaves*: Much like the Wyoming type, but often somewhat longer. Average length of basal leaves 11.83 ± 0.16 cm. *Culms*: Much like the Wyoming type but not overtopping the leaves quite so distinctly. A little above average number culms per plant 184.24 ± 9.14 .

length of basal leaves 17.67 ± 0.32 cm. *Culms*: A little above average number per plant, almost equaling the Nebraska type and more than the Oklahoma type. Average number per plant 197.30 ± 17.33 . *Spikes*: Long and narrow; often not overtopping the leaves. Often ascending. Average length 36.76 ± 0.53 mm. *Time of flowering*: Mid and late summer, often with two crops. *Plant vigor*: Very high.

(5) *New Mexico biotype* (fig. 53) closely related to *Bouteloua breviseta* Vasey. *Leaves*: Both basal and cau-

line long. Basal leaves not as numerous or as long as in the central Oklahoma type. Average length of basal leaves $16.93 \pm .46$ cm. *Culms*: Many, giving plants a distinctly stemmy habit. Average number of culms per plant 297.61 ± 27.06 . *Spikes*: Long, narrow, similar to those of *B. breviseta*; mostly arched even when immature. Average length 38.35 ± 0.62 mm. *Time of flowering*: Mid to late summer, often two distinct crops. *Plant vigor*: High, especially the rate of increase of basal area.

(6) *North Dakota biotype* (fig. 54) closely related to the Nebraska and Wyoming types. *Leaves*: Cauline, relatively few, spreading at wide angles from the culm. Basal leaves very short. Average length of basal leaves 6.22 ± 0.16 cm. *Culms*: Few per plant (62.55 ± 8.34). Short and distinctly overtopping the basal leaves. *Spikes*: Average length 29.60 ± 0.40 mm., thick and spreading horizontally from the culms. *Time of flowering*: Early summer, with only infrequently a second crop. *Plant vigor*: Poor.

Chromosome complements in blue grama.—After the 38 seed sources were classified into the six biotypes described above and were studied cytologically, an effort was made to correlate the two kinds of information. With one exception, the biotypes have proven not to be directly related to any one chromosome complement.

Triploid complements in blue grama (B. gracilis) 2n=21.—Plants from Antonito, Colorado (2030,³ fig. 53), of the New Mexico biotype were observed with $2n=21$. Since, from complement numbers to be discussed later, the basic number seems to be 7, this seed source is assumed to be a triploid. The chromosomes (fig. 20 and 48) in this plant ranged in length from 0.25 to 0.75 micron with most of the chromosomes being 0.50 micron long.

Tetraploid complements in blue grama (B. gracilis) 2n=28.—The tetraploid number ($2n=28$) was found in plants from nine seed sources. These were Lincoln, Nebraska (1958, fig. 41), Flagstaff, Arizona (2032), Galatea, Colorado (2034), Tucson, Arizona (2038, fig. 22), Hugo, Colorado (2338), Fort Collins, Colorado (2339), Hebron, North Dakota (2424), Kingman, Kansas (2433, fig. 21), and La Vegas, New Mexico (2566).

The biotypes represented in these tetraploids belonged to the Lincoln, Nebraska, salt flat type (1958 and 2433), the New Mexico (2032, 2034, 2038, 2566), the Nebraska (2338, 2339), and the North Dakota type (2424).

Pentaploid complements in blue grama (B. gracilis) 2n=35.—Plants from seven sources were found to be pentaploids ($2n=35$). The plants with this kind of complement were from Cheyenne, Wyoming (383), Ames, Iowa (969, fig. 24), Hartley, Texas (1725), Mandan, North Dakota (2049), Tucumcari, New Mexico (2157), and Limon, Colorado (2332). The biotypes represented were the Wyoming (383), the Nebraska (962, 969 and 2332), the Oklahoma (1725), the North Dakota (2049), and the New Mexico (2157).

Hexaploids and other ploidies in blue grama (B. gracilis).—Plants from twenty sources had the hexa-

ploid count of $2n=42$. These were from North Platte, Nebraska (378), Dickens, Iowa (379), Crystal Lake, Wyoming (380, fig. 46), Crawford, Nebraska (381), Raton, New Mexico (382, fig. 27), Cheyenne, Wyoming (386), O'Neill, Nebraska (969, fig. 47), Stillwater, Oklahoma (1180), Teton County, Montana (1524), Whitehall, Montana (1969), Mandan, North Dakota (1971, fig. 44), Craignyle, Alberta (1982), Mullen, Nebraska (1995, fig. 43), Las Cruces, New Mexico (2036, fig. 42), Hartley, Texas (2155), Mexican Springs, New Mexico (2156), New Amsterdam, Montana (2225, fig. 45), Center, North Dakota (2422), Killdeer, North Dakota (2423), and Julesburg, Colorado (2563). Five different biotypes were represented as follows: the Nebraska (378, 379, 1995), the Wyoming (380, 381, 386, 2563), the New Mexico (382, 2036, 2155, and 2156), the North Dakota (1524, 1969, 1971, 1982, 2225, 2422 and 2423) and the Oklahoma (1180).

Plants from but two sources have been found with chromosome numbers greater than $2n=42$. These were found in a plant from Enid, Oklahoma (1723, fig. 29) with $2n=61$, and a plant from Stillwater, Oklahoma (1724) with $2n=77$. Both plants were of the typical Oklahoma biotype.

The morphology of the chromosomes in blue grama.—Since the chromosomes in this species were so small, no definite morphological characters identifying them, such as constrictions and satellites, could be detected. Distinct differences in lengths of chromosomes in plants from the different seed sources did occur. In an attempt to classify these differences, at least one or more complete complements were drawn and measured for each seed source. The results of these measurements are shown in table 1.

There is no significant difference in the average complement length between the tetraploids and pentaploids, but there is a distinct difference between the mean length of the hexaploids and either the tetraploids or the pentaploids as shown in table 1. In all three ploidies, chromosomes measuring 0.75 micron were most frequent. The longest chromosomes (1.75 to 2.00 microns) were found in the tetraploid (fig. 22). The differences in total chromosome length within a given ploid are illustrated in figures 21 and 22. In figure 21 (2433 Kingman, Kansas) the total length of the 28 chromosomes is 25.75 microns; in figure 22 (2038 Tucson, Arizona) the total length of the twenty-eight chromosomes is 31.75 microns. Similar differences in the pentaploids are shown in figure 23 (962 Ames, Iowa) with a total length of 29.75 microns. Figures 25, 26, 27 and 28 show similar increasing total complement lengths in hexaploids.

BIOTYPES AND CHROMOSOME COMPLEMENTS IN SIDE-OATS GRAMA.—The chromosome complements of plants from 32 seed sources of side-oats grama (*B. curtipendula*) were studied. When grown in the same nursery it was possible to classify the plants from all sources into five distinct biotypes. These are designated in this report as the Temple, Texas (fig.

³ These numbers are the accession numbers of the Nursery Section, Operation Division, Soil Conservation Service, U. S. Department of Agriculture, Lincoln, Nebraska.

60), the Nebraska (fig. 63), the Oklahoma (fig. 64), the southern Arizona (fig. 65), and the North Platte, Nebraska, biotypes (fig. 66). These appeared to have more intermediates than those described for blue grama (*B. gracilis*), but each was readily recognized when growing side by side under cultivation. The differences and similarities are described and compared below.

The descriptions of five biotypes of side-oats grama.—

(1) *Temple, Texas, biotype* (fig. 60). *Leaves*: Mostly basal and very long, cauline, long and coarse. Average length of basal leaves 26.28 ± 0.75 cm.⁴ *Culms*: Few in number and short, barely overtopping leaves, internodes short. *Inflorescence*: Often not exerted, those emerging well filled with spikes. *Plant vigor*: Especially high first two seasons.

(2) *Nebraska biotype* (fig. 63) closely related to the Oklahoma type. *Leaves*: Of average length and abun-

⁴ These are means and standard errors for use in determining significant differences by use of the same formula discussed before for blue grama.

dance, about equally distributed between cauline and basal leaves. Average leaf length 17.28 ± 0.38 cm. *Culms*: Average number per plant, these distinctly overtopping the leaves. Average height of culms 57.17 ± 0.79 cm. *Inflorescence*: Average length 23.20 ± 0.48 cm. Well filled with spikes. *Plant vigor*: Average.

(3) *Oklahoma biotype* (fig. 64) closely related to the Nebraska type. *Leaves*: Of average length, comparable to the Nebraska type but leaves coarser and more abundant. Average length 17.27 ± 0.41 cm. *Culms*: Many per plant, compared to the Nebraska type, these usually longer. Average height 39.71 ± 1.13 cm. *Inflorescence*: Average length 25.22 ± 0.61 cm.; well filled with long spikes. *Plant vigor*: Above average.

(4) *Arizona biotype* (fig. 65). *Leaves*: Average number of long culm leaves, basal ones sparse, weak and lax. Average length 15.65 ± 0.26 cm. *Culms*: Many, very long, weak, often geniculate at the base, spreading. Average height 73.65 ± 1.13 cm. Long internodes. *Inflorescence*: Long with long spikes loosely arranged. Average length 24.08 ± 0.43 cm. *Plant vigor*: High first year but not winter hardy in Nebraska.

(5) *North Platte, Nebraska biotype* (fig. 66). *Leaves*: Basal few and short, very few short culm leaves. Average leaf length 9.44 ± 0.49 cm. *Culms*: Shorter and fewer than average, distinctly overtopping the leaves. Average height 42.52 ± 0.96 cm. *Inflorescence*: Short, average length 13.21 ± 0.54 cm. *Plant vigor*: Very weak.

The chromosome complements in side-oats grama.—After plants from the thirty-two seed sources of side-oats grama had been studied cytologically, the results were related to the five biotypes. As in blue grama the biotypes were not found to have distinctly characteristic chromosome complements.

Hexaploid and near hexaploid complements in side-oats grama.—Plants from four sources had aneuploid complements of $2n=40$. These were from O'Neill, Nebraska (373, fig. 12), McGregor, Iowa (958, fig. 10), El Reno, Oklahoma (1497), and Seiling, Oklahoma (2562, fig. 11 and 37). Two biotypes were represented, the Nebraska (373 and 958) and the Oklahoma (1497 and 2562).

Hexaploids ($2n=42$) were found in plants from eighteen sources. These were Algona, Iowa (374), O'Neill, Nebraska (375), Kuippa, Texas (1179, fig. 13), Crockett County, Texas (1730), Wanoka, Oklahoma (1732), Aztec, New Mexico (2029), Beulah, Colorado (2035), Hays, Kansas (2158, fig. 14), Oklahoma (2163), Harmon, North Dakota (2335), Colorado Springs, Colorado (2343), Clinton, Oklahoma (2356, fig. 16), El Reno, Oklahoma (2358), Stillwater, Oklahoma (2359), Columbus, Nebraska (2409), Lindsborg, Kansas (2412), Altoona, Kansas (2558), and Temple, Texas (2561). These

plants all belonged to but two biotypes, the Nebraska (374, 375, 376, 971, 1732, 2035, 2335, 2409, 2412 and 2558) and the Oklahoma (1730, 2158, 2163, 2343, 2356, 2358 and 2359).

Polyploid types higher than the hexaploid in side-oats grama.—One aneuploid type was found with 45 chromosomes (fig. 17). This plant came from Chickasha, Oklahoma (2560), and belonged to the Oklahoma biotype.

One plant from Temple, Texas (1728), with $2n=56$ (fig. 18) was found. This plant belonged to a distinctive type called here the Temple, Texas, biotype (fig. 60). Two plants, one from Whitset, Texas (1729), and one from Flagstaff, Arizona (2028), were found with $2n=70$. The plant from Whitset belonged to the same biotype as the Temple, Texas, plant (fig. 60), and the Flagstaff plant had the characteristics of the southern Arizona biotype (fig. 65). One plant with $2n=98$ (fig. 19) from Galatea, Colorado (2336), was intermediate between the Nebraska and the Arizona biotypes.

The morphology of the chromosomes in side-oats grama.—Differences in total length of chromosomes per complement were found as commonly in side-oats grama as in blue grama. Table 2 shows the tabulated measurements of the complements in four aneuploid plants and sixteen hexaploids. From this table it is evident that the average total length of chromosomes in the aneuploids ($2n=40$) and the hexaploids differs by 5.18 microns. In both types of complement, most of the chromosomes were either 0.50 mi-

cron or 0.75 micron long. No chromosomes longer than 1.75 microns were found.

The differences in total length of chromosomes within the $2n=40$ type are illustrated in figure 10 (McGregor, Iowa, 958; total length 19.25 microns), figure 11 (Seiling, Oklahoma, 2562; total length 26.50 microns) and figure 12 (O'Neill, Nebraska, 373; total length 29.25 microns). In the hexaploids four plants are illustrated (fig. 13, 14, 15 and 16). Each succeeding complement differs from the one preceding by at least 4 microns.

CHROMOSOME COMPLEMENTS IN FIVE ADDITIONAL SPECIES.—In *B. breviseta*, it was found that the chromosome number was $2n=21$ (fig. 1 and 30). The plant from which this count was made (fig. 57) was typical of the species with its many stems, few basal leaves, long culm leaves, and long spikes.

Plants of *B. eriopoda* from three different seed sources were investigated and all had $2n=21$ chromosomes. The seed sources were Tucson, Arizona (1607), Las Cruces, New Mexico (2036), and Belen, New Mexico (2154). The plant from Tucson, Arizona (1607) had chromosomes ranging in length from 0.25 to 1.50 microns with an average length of 1.00 micron (fig. 2 and 31), which is considerably longer on an average than those counted in *B. breviseta*. These plants also had two small spherical chromosomes in each complement (fig. 2). These appeared to be characteristic.

The plants from the three seed sources of *B. hirsuta* studied had $2n=21$ in the Hebronville, Texas, $2n=37$ in the Hays, Kansas (2164), and $2n=42$ in the Stillwater, Oklahoma (1498) biotypes. The Hebronville complement (fig. 3 and 32) had chromosomes ranging in length from 0.50 to 1.50 microns, with the 0.75 micron class most frequent.

Differences in the combined length of all the chromosomes in each complement were shown by the fact that the total length in the Hebronville, Texas, plant was 18.00 microns; in the Hays, Kansas, plant 22.25 microns; and in the Stillwater, Oklahoma, plant 31.50 microns.

The one plant of *B. rigidiseta* studied was from Denton, Texas (1977). It had $2n=35$ chromosomes (fig. 6 and 59). These ranged in size from 0.25 to 2.00 microns, most of which were 1.00 micron long. The total chromosome length of the 35 chromosomes was 31.75 microns.

In the one plant of *B. rothrockii* from Tucson, Arizona (1385), 22 chromosomes were found (fig. 7 and 58). These had much the same morphology as those found in *B. breviseta* (fig. 1).

PROCHROMOSOMES IN BLUE GRAMA AND SIDE-OATS GRAMA.—Although exhaustive investigations of prochromosomes in these species have not been made, a few definite observations can be reported here. Almost all resting cells in the root tips of both species are characterized by distinct prochromosomes. These bodies vary in shape from small spherical bits of chromatin about 0.20 micron in diameter to dumbbell-shaped bodies and short rods 1.25 microns long. Their shape seems to depend on how recently the nuclei of which they are a part have undergone mitosis. In all cases observed the prochromosomes were about equally distributed about the periphery of the nucleus. They were easily counted and drawn, but an accurate count was difficult because the nucleolus often hid one to several.

In one plant of blue grama from Teton County, Montana (1524), with a metaphase root tip count of $2n=42$, 34 spherical to rod-like prochromosomes varying in length from 0.25 to 1.25 microns were drawn and measured. In another plant from Dickens, Iowa (379), with a metaphase root tip count of $2n=42$, 35 spherical to dumbbell-shaped prochromosomes were observed. In the first, the nucleolus measured 3.00 microns in diameter and in the second 3.50 microns, either of which doubtless shielded five or six prochromosomes.

In one plant of side-oats grama from Norton, Kansas (376), with a metaphase root tip count of $2n=28$ (fig. 8), 28 nearly spherical prochromosomes (fig. 35) were observed. In another plant from Wanoka, Oklahoma (1732), with a metaphase root tip count of $2n=42$, 38 prochromosomes were present. In both these cases the prochromosomes were spherical bodies 0.20 to 0.30 micron in diameter.

DISCUSSION.—The studies reported in this paper on the biotypes of blue grama agree with those of Griffiths (1912) concerning the distinctness of the northern low sod type form and the tall vigorous bunchgrass typical of the lower elevations in the southwest. The observations made here do not agree with those of Griffiths regarding the similarity of the two forms under cultivation. In this study, individual plants of the two have maintained their individuality

⁶ Photographs furnished through the courtesy of the Soil Conservation Service, U. S. Department of Agriculture. The marks on the rule in figure 49-57 are 6 inches apart.

under cultivation for five years. The chromosome complements in the two forms tend to be different, but there are many exceptions. As a rule the northern form tends to be hexaploid, while the southwestern one is often tetraploid or pentaploid. One triploid has been found also.

In addition to the northern low sod form and the southwestern bunch grass already discussed, four other biotypes have been described and studied cytologically in this report. Of these, the Wyoming and Nebraska types are most closely related to that of the northern prairie. The other two (the Oklahoma and Lincoln, Nebraska, biotypes) appear to be entirely distinct from either the northern or southwestern plants but are closely related to each other. Both are strong bunch grasses but with unusually long basal leaves. Cytologically, these two types are unstable and tend to have high polyploid chromosome numbers.

The fact that plants grown from different seed sources produce distinctive plants as reported by Savage (1939) and Hoover (1939) agrees with observations made here. This fact indicates a high degree of adaptation to particular habitats and is a factor that should be carefully considered in the domestication of such species as side-oats grama and blue grama.

Since plants grown from seed from different localities are distinctive and are able to maintain their peculiar characters for as long as five years when grown in one environment, their chromosomes undoubtedly have structural differences. Just what these differences are can only be analyzed after a critical examination of meiotic behavior. This awaits further study.

Griffiths (1912) noticed but did not describe the variation in side-oats grama between plants from different areas. This has been substantiated by the writer. Besides, all the plants from a wide range have been classified and grouped into five typical biotypes. These have been studied cytologically. Since this has shown that the five biotypes do not have individually characteristic chromosome complements, it is assumed that differences between biotypes may be due to factors within individual chromosomes. However, a critical analysis of meiosis in the pollen mother cells will be necessary to discern adequately these differences.

The predominance of the low chromosome numbers ($2n=21$) in *B. breviseta*, *B. eriopoda*, *B. hirsuta* and *B. rothrockii* ($2n=22?$) coupled with the fact that these are often dominant species in the southwestern states and northern Mexico is further evidence that this area is near the center of distribution for the genus. The triploid New Mexico biotype of blue grama (*B. gracilis* 2030) from Antonito, Colorado, is closely related to the other southwestern species through *B. breviseta* inasmuch as both have similar growth habits and the same number of chromosomes ($2n=21$). Since only a relatively few plants representative of these species have been

studied, it is entirely possible that variation in chromosome numbers within these species would be found by intensive search.

The hexaploids in both blue grama and side-oats grama are the most common ploidies, the most aggressive and the most widely distributed.

It is also significant that in both species, the few higher ploidies found came from either central Oklahoma, Texas or southern Arizona. This indicates that the production of new types through various chromosomal aberrations is probably still a dynamic process in this region.

The hexaploid count of $2n=42$ found by the writer in the Nebraska biotypes of both blue grama and side-oats grama substantiates the earlier reports of Humphrey (1937) and Neilsen and Humphrey (1937) made on plants grown from seed from the Great Plains.

The fact that most chromosome complements studied by the writer as well as by others have been multiples of 7, would indicate that this is the basic number in the genus. Further study of plants with larger chromosomes, in which the constrictions can be seen, is needed definitely to substantiate this. Since tetraploids in both blue grama and side-oats grama ($2n=28$) have been found, it is likely that the diploid type of $2n=14$ will be found by further search especially in the southwestern biotypes.

The common occurrence of prochromosomes in resting cells of both meristematic and differentiated tissues in blue grama and side-oats grama should prove of considerable value to the plant breeder if it can be conclusively shown that their number is the same as the number of chromosomes. The observations reported here would indicate that such may be the case and agree with earlier observations by other workers on other genera with small chromosomes (Eichhorn, 1931; Doutreligne, 1933; Raghaven, 1938; Smith, 1934; and Zeeuw, 1935).

SUMMARY

The somatic chromosome complements in the genus *Bouteloua* have been investigated in eighteen biotypes belonging to seven species. One hundred fourteen plants from 85 seed sources were included in the study.

Chromosome numbers varied from $2n=21$ to $2n=98$.

The chromosome numbers found in the seven species are: *Bouteloua breviseta* Vasey, $2n=21$; *Bouteloua curtipendula* (Michx.) Torr. $2n=28, 35, 40, 42, 45, 56, 70$ and 98 ; *Bouteloua eriopoda* (Torr.) Torr. $2n=21$; *Bouteloua gracilis* (H.B.K.) Lag. $2n=28, 35, 42, 61$ and 77 ; *Bouteloua hirsuta* Lag. $2n=21, 37$ and 42 ; *Bouteloua rigidiseta* (Steud.) Hitchc. $2n=35$ and *Bouteloua rothrockii* Vasey $2n=22$.

Six biotypes of blue grama (*B. gracilis*) have been described and their chromosome complements studied. No definite relation between complements and

biotypes was found. One biotype often had two or more different chromosome complements.

All the chromosomes in one or more complements of seven tetraploid, six pentaploid and sixteen hexaploid plants of blue grama (*B. gracilis*) were measured. Chromosome lengths varied from 0.25 to 2.00 microns, most of which were 0.50 to 0.75 micron.

The average total chromosome length per complement in blue grama varied from 27.14 microns in the tetraploids and 27.83 microns in the pentaploids to 32.34 microns in the hexaploids. In the same ploid, total lengths differed by as much as 9.75 microns in the tetraploids, 11.75 microns in the pentaploid and 15.25 microns in the hexaploid.

Five biotypes of side-oats grama (*B. curtipendula*) have been described and related to their chromosome complements. No direct correlation was found.

All the chromosomes in one or more complements of four aneuploid ($2n=40$), and sixteen hexaploid ($2n=42$) plants of side-oats grama were measured. Chromosome lengths varied from 0.25 to 1.75 microns most of which were 0.50 to 0.75 micron. The average total chromosome length per complement in the aneuploid ($2n=40$) was 25.18 microns; in the hexaploid ($2n=42$) 30.36 microns. In the same ploid total lengths varied by as much as 10.00 microns in the aneuploid ($2n=40$) and 15.00 microns in the hexaploid.

Prochromosomes in resting cells in both meristematic and differentiated tissue were found to be common. This was especially true in both blue grama (*B. gracilis*) and side-oats grama (*B. curtipendula*). The limited observations made indicated that the number of prochromosomes equals the number of chromosomes.

STUDIES OF THE GROWTH OF POLLEN WITH RESPECT TO TEMPERATURE, AUXINS, COLCHICINE AND VITAMIN B₁¹

Paul F. Smith

ALTHOUGH NUMEROUS reports have been made in recent years concerning the influence of various chemical stimulants on plants, relatively few have dealt with the germination and growth of pollen. Apparently no one has mentioned the inter-relation of temperature and chemical stimulation in connection with pollen physiology. In the writer's experience with the culture of pollen certain facts have been brought out concerning growth stimulation by means of chemicals and temperature, as well as the inter-relationship of these two factors. Important factors in the technique of culturing pollen also have come to light. It is the purpose of the present paper to report some of these findings.

MATERIALS AND METHODS.—The pollen of *Lathyrus odoratus* (sweet pea), *Tradescantia occidentalis* (spiderwort), *Antirrhinum majus* (snapdragon) and *Bryophyllum Daegremontianum* were used as test material in preliminary work. Inasmuch as the responses of all four species were essentially similar in most respects, extensive studies were made only with the latter two (*A. majus* and *B. Daegremontianum*), for which data, figures and discussion will be presented here.

Although many of the physiological studies of pollen in the past have been made by the hanging-drop technique (Brink, 1925; Vom Berg, 1929; Cooper, 1939; Smith, 1939), later experiments have shown that the growth of pollen is seriously handicapped by this method. It was found, for instance, that with growth periods of four hours in hanging drops the tube length of the pollen of *Tradescantia occidentalis* was only about one-half as great as that on sugar-agar. Consequently, the sugar-agar technique (Eigsti, 1940a) was used throughout the following experiments. Since a concentration of 0.75 per cent agar was found adequate to support the pollen grains and tubes on the slides, this concentration was used with the appropriate amount of sucrose. For snapdragon a 10 per cent sucrose solution proved satisfactory and with *Bryophyllum* a 3 per cent solution was used.

In choosing pollen, fresh flowers in the late bud stage were brought into the laboratory in the evening. Such flowers were usually at the proper stage for use the next day. Thus it was possible to avoid obtaining old pollen and to prevent the loss of pollen caused by handling the flowers after dehiscence had taken place. The snapdragon transpired so rapidly that it was necessary to keep it under a par-

tially closed bell jar to prevent wilting and scattering of pollen in the dry atmosphere of the room.

Previous workers have encountered fluctuation in the growth responses of pollen. Brink (1924a) mentions the "unexplained vagaries" and "variabilities in the growth reactions of pollen." In the present work, great variation was noted unless special attention was given to the selection of pollen. A large number of slides were inoculated by using the pollen from a single anther for each slide. Two types of variation were found: (1) pollen of different flowers might differ in quality or magnitude of response, and (2) pollen from different anthers of the same flower might give different responses. In snapdragon, little or no variation was observed in the responses of the pollen from the anthers of a single flower. In *Bryophyllum*, however, pollen from one of the eight anthers was frequently partially sterile and gave poor germination. Consequently, pollen from all the anthers of one flower of this species was combined and inoculation made from the mixture. Thus, in either case a single flower furnished the pollen for each test series (*i.e.*, the three auxins, the colchicine, the vitamin B₁ and the control slides). Such a procedure should make different responses within any one series attributable solely to the effect of the test substances in the media. In attempting to reproduce such a series of tests, in order to obtain similar results with other flowers, the variability between individual flowers was encountered. Pollen from flowers of a comparable age (as judged from the time of anther dehiscence) is much more likely to give uniform responses than if their age is disregarded. Apparently there is a time in the development of pollen when all metabolic functions harmonize in such a way that germination and growth of tubes will result if the grain is in a suitable environment. This stage in the physiological development may precede, coincide with, or follow dehiscence. In some species (*e.g.*, periwinkle [*Vinca rosea*]) the pollen often germinates within the anthers. Snapdragon pollen gives best germination shortly after dehiscence and becomes what we may term "old" pollen within three to four hours. *Bryophyllum* possesses a waxy pollen which germinates most satisfactorily several hours after dehiscence and retains the ability to germinate for forty-eight hours or more.

The significant thing about the age factor is that best germination and growth of tubes took place only within these age limits. In snapdragon, young pollen (pollen from flowers which were expanded but with anthers undehiscent) germinated poorly, yielding a very low percentage of germination. The resulting tubes grew slowly and unevenly and never attained the length ordinarily reached by ripe pollen. The tubes from such pollen were extremely

¹ Received for publication August 3, 1941.

This study was conducted at the University of Oklahoma during the years 1938–1940. The writer is grateful to Dr. O. J. Eigsti for advice and criticisms during the course of the investigation and to Dr. G. L. Cross for extending the laboratory facilities of the Department of Botany. Thanks are also accorded to the Oklahoma Chapter of the Society of the Sigma Xi for a research grant which made possible the procurement of four germination chambers.

crooked and exhibited a strong tendency to burst after about two hours' growth. Old pollen (pollen from anthers which had dehisced at least four to six hours previous to inoculation in the case of snapdragon) invariably gave difficulty, at least in quantitative work. Such pollen was characterized by a low percentage of germination and short, extremely crooked tubes.

The majority of flowers chosen by this procedure furnished pollen that gave reasonably uniform responses. It became possible to tell by examining the control slide whether the pollen was at the proper stage of development to give optimum growth. Thus, by using one flower for a complete series and by using

out favorable stimulation in more dilute solutions. As an arbitrary measure a 1:25,000 dilution was chosen for further tests.

Colchicine was used in a 1:10,000 (0.01 per cent) concentration with the pollen of snapdragon, chiefly because this dilution is frequently used in cytological studies. In certain tests with *Bryophyllum*, however, other concentrations were used. In the 25°C. and 35°C. test series with this pollen, three concentrations were used (1:1,000, 1:10,000 and 1:20,000).

The time allowed for growth was chosen after preliminary work with the pollen, and its selection was based on the length attained by the tubes. The experiments were stopped before the tubes grew too

TABLE 1. *Effects of various concentrations of 3-indole acetic acid and vitamin B₁ on the germination and tube length of snapdragon pollen.*

Vitamin B ₁	1:100,000	379	58.9	347

many series it was possible to discard the occasional series from flowers which were not of correct physiological age. With these precautions one could be relatively certain that the measured series were showing reactions to the conditions under which they were grown (i.e., presence or absence of the test substances or growth at particular temperatures) and that these reactions did not result from varying physiological conditions of the pollen. Where such precautions were neglected, there was neither harmony nor regularity in the responses of the pollen of one series, nor was any comparison possible between similar slides of successive series.

Preceding the quantitative experiments it was necessary to determine the optimal concentrations of the test substances. Table 1 shows measurements made from cultures of snapdragon pollen with various concentrations of 3-indole acetic acid and vitamin B₁ at 25°C. The same tests were made with *Bryophyllum* and similar results were obtained. In both cases, concentrations of 3-indole acetic acid stronger than 1:50,000 were toxic, i.e., caused decreased germination, retarded elongation, and caused bursting and distortion of tubes. Weaker concentrations were favorably stimulative with a maximum response in the 1:100,000 dilution. Consequently, this dilution was used in the present studies.

By similar methods, vitamin B₁ was found to be toxic in a concentration of 1:10,000 but was with-

long to be measured accurately. With a growth period of 5½ hours for snapdragon pollen at the optimum temperature there were relatively few tubes longer than the diameter of the low power microscopic field. With *Bryophyllum* a three-hour culture period was sufficient. Growth was stopped by removing the slides from the germination chamber and placing them on a warming plate (50°C.). In this way, the excess moisture was removed in three to five minutes and the slides were ready for mounting in an aceto-carmine mounting medium (Zirkle, 1937). Slides prepared in this way were especially satisfactory for study because there was no disturbance of the tubes from the original growth pattern, and there was no loss of tubes or ungerminated grains, as usually results when a dip staining method is used.

For experimentation with different temperatures the germination pans were placed in constant temperature chambers, and the temperatures were adjusted so that the readings at the locus of the slides were 15°C., 20°C., 25°C., 30°C. and 35°C., respectively. The temperatures were controlled to within ±0.5°C. Therefore, with each pan holding 60 slides and with five temperatures being used, a total of 300 slides was used for each run. Each test substance was represented ten-fold at each temperature with each run. The runs were repeated numerous times.

For counts of percentages and measurements of tubes the low power field (100×) of a compound mi-

croscope was used. Fields for study were chosen at random among those containing approximately 50 grains. This rule was instituted for purposes of producing uniformity, since it eliminated the counting of (1) very thickly populated fields, where germination and growth were affected by crowding, and (2) those fields containing only a very few grains, where growth was less uniform. (Further mention of the desirability of a uniform distribution of grains is made in the discussion of the auxin series.) Pollen of the two species used is sufficiently fine so that more

than 1,000 grains could be counted in one field. The measurements were made with an ocular micrometer, using a low power lens for length measurements and an oil immersion lens (990X) for measurement of tube widths. Since the diameters of the tubes were often not uniform, only the greatest diameter of each tube was measured.

The pH of each solution was determined at the time of inoculation. This was done colorimetrically with occasional checks by the calomel electrode potentiometer.

RESULTS AND DISCUSSION.—Less than 1 per cent germination occurred at 15°C. in all cases with pollen of snapdragon, and the tubes were extremely short and narrow. The only discernible response at this temperature was that germination occurred less frequently in the colchicine medium than in the others. Because germination was so slight and the resulting tubes were rarely more than twice the diameter of the grains in length, no counts or measurements are presented.

The results for the pollen of snapdragon are presented in tabular form for the 20°C., 25°C. and 30°C. series (tables 2, 3 and 4). Also, figures 1 to 12 illustrate some typical responses for these series. The 35°C. series showed virtually complete bursting of the tubes which rendered the task of counting and measuring a hopeless one. It was perceptible, however, that the character of the tubes resembled the corresponding series at 30°C. except that the tubes were shorter and the percentage of germination was less.

The observed responses of this pollen to temperature were the percentage of germination and the length, shape, and amount of bursting of tubes. At 20°C. the mean germination was 27.5 per cent in the control series as compared to 59.0 per cent at 25°C. and 46.8 per cent at 30°C. These data indicate that

25°C. is more favorable for germination than 20°C. or 30°C. Likewise, the lengths of tubes were found to attain their maxima at 25°C. Some of the tubes at that temperature were at least 144 microns longer than the longest of the 20°C. series and at least 288 microns longer than the longest of the 30°C. series.

The difference in the shape of tubes at different temperatures was striking. At 15°C. the tubes were very short, extremely narrow, and uniform in size throughout their length. At 20°C. and 25°C. (fig. 1 and 5) the tubes were broader but still uniform in width. At 30°C. an altogether different response was found. Here the intine penetrated the exine in a constricted form and then gradually enlarged or "battered" so that it became a club-shaped structure with the diameter of the distal part of the tube usually exceeding the diameter of the grain itself (fig. 9). At 35°C. the same characteristic bloating occurred, except that the swollen tubes nearly always burst, thereby allowing the cytoplasm to escape. These characteristics of increased temperatures (decreased germination, shortening and broadening of tubes, and high percentages of bursting) were found to exist with the other species studied, although the magnitude of swelling and the temperatures at which the responses occurred were specific for each. *Bryophyllum*, for example, showed little difference at

30°C. from 25°C., but at 35°C. the responses to increased temperature began to appear. Various workers (Buchholz and Blakeslee, 1927; Dorsey, 1919; Anthony and Harlan, 1920, and others) have studied the relation of temperature to the rate of pollen tube elongation but none mentions the increase in diameter with increased temperature. Vom Berg (1929), working with *Impatiens Holstii*, reported that 32°C. was "less favorable" for germination and elongation than 20°C. His test temperatures were 10°C., 20°C. and 32°C.

In all cultures of snapdragon at 30°C. there was a peculiar response within the swollen portion of the tube. Quite frequently cross striations appeared which were apparently cytoplasmic material and not callose plugs (see fig. 9a, 11a, 12c). This response was not found with any other species.

In consideration of tube width, percentage of germination and the occurrence or absence of bursting, 25°C. was more favorable than the other temperatures for the growth of the pollen of snapdragon.

The response to stimulation by auxin, as with the response to temperature change, is also an individual reaction of the species concerned. Pollen is naturally furnished with auxin in greater or lesser amounts, and if the natural supply is adequate the provision of additional auxin should cause little, if any, stimulation. The writer (Smith, 1939) found that 3-indole acetic acid induced the pollen of *Pinus Austriaca* to germinate, whereas germination did not occur in the control. The percentages of germination and the rates of elongation of the tubes of the pollen of other species were also reported. Cooper (1939) and others have noted mild stimulation of germination by the auxins. In the present study, with snapdragon, the auxins showed themselves to be favorable additions to the culture medium, although the response was less pronounced than with *Bryophyllum*. With each auxin and at each temperature, longer tubes, narrower tubes and higher percentages of germination were found than in the corresponding control (see tables 2, 3 and 4). The frequency of the tubes in the various length-classes is noteworthy. In each case the percentage of short tubes (the 0-1 and 1-2 groups) was less than in the control. There was a general stimulating effect so that, although the germination was not greatly increased, the tubes elongated more rapidly and attained a greater length than did those of the control.

Chemotropic effect of stigmas and other flower parts on the growth of pollen was observed by Molisch (1893). Subsequent investigations have shown many cases of similar responses, although they are

not universal. That growth of tubes is enhanced by clustering of the grains was noted by Brink (1924b). This was observed with many species, and none of those tried failed to respond in this way. He reports, furthermore, that germination is quite frequently much more profuse when the grains are grouped closely together. In the present work, the same phenomenon was observed with the pollen of snapdragon and *Bryophyllum*. In the control, the vitamin B₁ and the colchicine series, the tubes from grains that occurred in clusters had a marked tendency to grow into the cluster. If a tube of this cluster-arrangement happened to be pointed outward by chance, it usually bent inward and grew back into the cluster. Germination was also usually enhanced by the grouping of grains. Since the concentration of auxin can reasonably be expected to be greater in regions thickly populated with grains, it is apparent that tubes are stimulated to grow toward the auxin center just as Molisch (1893) observed them to grow toward stigmatic tissue.

The tubes of the auxin series were more nearly straight, with less tendency to coil and bend in their outward growth, than were the control tubes. A common response was for the tubes to radiate away from the cluster. Inasmuch as the medium had been supplied with an external supply of auxin, the tubes were evenly stimulated and grew in the direction in which they started. This results in growth away from the cluster even though the tube may have to go through the cluster and emerge on the other side, should it be pointed toward the cluster when germinating. Under such conditions, unilateral hormonal stimulation from other grains and tubes was overshadowed. Such a result was seen many times.

Of the three auxins, 3-indole acetic acid seemed to have a stronger stimulatory effect on snapdragon pollen than the 3-indole butyric or naphthalene acetic acid. The latter substance showed the least stimulatory effect.

No evidence of favorable stimulation by vitamin B₁ was revealed in these experiments. Dandliker, Cooper and Traub (1938) state that in their work with pollen of *Carica papaya* the influence of vitamin B₁ was one of accelerating the rate of early tube growth, although in certain varieties of this pollen they found no stimulation. In the present investigation, no attempt was made to study the early growth of tubes, but the results show that the addition of vitamin B₁ had little if any effect upon the final percentage of germination and length of tubes. The pH of this medium was 5.6, which was considerably more acidic than the control's 6.5, and may well be respon-

Fig. 13-24. *Bryophyllum*. Again each column represents one temperature and each row represents one culture medium.—Fig. 13, 17 and 21. Control.—Fig. 14, 18 and 22. Three-indole acetic acid series.—Fig. 15, 19 and 23. Vitamin B₁.—Fig. 16, 20 and 24. Colchicine. Note the broadening effect in each series with each temperature increase. The long tubes of this pollen show a broadening of the basal part of the tubes while the short tubes show a uniformly large diameter in the 35°C. cultures. In figure 18, note the strikingly long, narrow tubes of the 3-indole acetic acid series as compared to the other members of this temperature series (17, 19 and 20).—Fig. 20 is of the 0.1 per cent colchicine series and shows the extreme amount of bursting found with this concentration.—Fig. 16 and 24 are 0.01 per cent colchicine cultures. The similarity of the tubes of the control series and the vitamin B₁ series is quite evident. Magnification approximately 77X.

sible for the small difference. A slightly greater tube diameter than that of the control cultures was the only obvious difference. That this difference in diameter may well have been due to the pH change accompanying the addition of the vitamin (thiamin hydrochloride) was indicated by acidifying some of the control culture solutions to 5.6 with HCl. In this medium there was a similar increase in tube diameter.

With the colchicine series, in all three temperatures, the percentages of germination were decidedly less than those in the control. Inspection of tables 2, 3 and 4 reveals that, in each case, the length-class with the largest frequency is one unit less than the corresponding class in the control. This is a reflection of the fact that colchicine depresses germination and tube elongation, producing a larger population in the shorter categories. Figure 4 shows an interesting and characteristic colchicine reaction at low temperatures, that is, the coiling of the tube (a). Also, rough and crooked tubes (b) are common in the 20°C. cultures containing colchicine. At 15°C. and 20°C. no noticeable increase in tube width was perceptible. At 25°C. many of the tubes showed abnormal swelling or bloating which resembled the response of all the other series at 30°C. At 30°C. the bloating effect was magnified, and the swollen tubes frequently broke at the tips and the cytoplasm was forced out (fig. 12 a, b). Bursting of the tubes of the other 30°C. series was rarely found. Eigsti (1940b) observed that swollen tubes resulted from colchicine treatment of *Polygonatum*.

Pollen of *Bryophyllum* was found to be less sensitive to temperature changes than was that of snapdragon. As a result, only the 15°C., 25°C. and 35°C. cultures were counted and measured (tables 5, 6 and 7). Photomicrographs of the same four series presented for snapdragon are shown, the microscopic fields representing a random sample of the particular group (fig. 13 to 24).

At 15°C. 28.8 per cent germination and good growth of *Bryophyllum* pollen occurred, and the three-hour culture period, necessary to produce maximum development at higher temperatures, was sufficiently long to allow considerable growth at this lower temperature. At 25°C. 61.5 per cent germination and at 35°C. 43.7 per cent germination resulted. Cultures were tried at 45°C. but gave virtually complete bursting of both grains and tubes. The tubes of this pollen were rather smooth and inclined to moderate curvature in their growth patterns. Probably the most striking response to the increase in temperature, in addition to the greater mean tube width, was the very uneven and irregular growth at 35°C. In both the 15°C. and 25°C. series the tubes were more or less uniform in length with few unusually short or particularly long tubes. At 35°C., however, there was a very diverse mixture of tube lengths from very short to quite long (fig. 21). The longest tubes observed in the controls were in this series and were at least 288 microns longer than the longest in the 25°C. series. The short tubes of this group had a greater diameter than the long ones (again see fig. 21). Also,

the longer tubes were broader in the region nearest the grain and gradually tapered out at the extremity. Thus, although the tubes of both *Bryophyllum* and snapdragon exhibited a broadening response to increased temperature, the methods of response were opposite. Snapdragon produced tubes that were nearly isodiametric at 20°C. and 25°C. and then responded with a great broadening at the outer extremities of the tubes at 30°C. *Bryophyllum*, although isodiametric at 15°C., began to show an unevenly increased diameter at 25°C. and a still greater enlargement at 35°C. The broadening in this case was at the proximal end of the tube (compare fig. 13, 17 and 21).

As has been noted above, pollen of *Bryophyllum* gave a more marked reaction to the addition of auxin to the medium than did that of snapdragon. The percentages of germination were greater in the presence of auxin and the mean lengths of the tubes were considerably greater. Again 3-indole acetic acid was apparently more stimulating than naphthalene acetic acid but had an effect about equal to that of 3-indole butyric acid. It is evident that the greatest stimulation occurs at the temperature (25°C.) that evoked the optimum growth in the control. Here 85 per cent germination was found in the 3-indole acetic acid series and a mean tube length of 562 microns, in contrast with 61.5 per cent and 334 microns in the control. Visible evidence of increased germination may be seen in figure 18 where relatively few ungerminated grains appear as compared to figure 17. A third response to the auxins (besides increased germination and tube length) was the relatively smaller tube width at all temperatures than in the corresponding control. Accompanying a smaller tube width is the fact that the tubes were again relatively straighter in the auxin series. The tendency for a great mixture of tube lengths at 35°C., as mentioned in the case of the control series, existed in the auxins as well as in the vitamin B₁ and colchicine series. Indeed, the longest tubes found with *Bryophyllum* pollen were in 35°C. 3-indole acetic and 3-indole butyric acid series, where a few tubes attained a length of over 1,700 microns in the three-hour culture period. The predominance of shorter tubes, however, cut down the mean length to less than that of the 25°C. group.

As with snapdragon, little difference between the vitamin B₁ series and the control was noticeable. The percentages of germination, the mean lengths of the tubes and the general character of the tubes of the two series were very much alike. A consistently greater tube diameter was again the only prominent response. The similarity of the two series is seen in a comparison of figures 17 and 19.

In the colchicine series of *Bryophyllum* pollen, three concentrations of colchicine were used in the 25°C. and 35°C. tests. At 15°C. the 0.01 per cent (1:10,000) concentration caused almost 7 per cent decrease in germination, a slightly greater mean diameter and extreme crookedness of the tubes (fig. 16). At 25°C. these same general reactions were more pronounced with an increase in the concen-

tration of colchicine. The 0.1 per cent (1:1,000) concentration greatly reduced germination, retarded growth and caused extensive bursting of tubes (see fig. 20). The 0.005 per cent (1:20,000) concentration showed responses that were very similar to the control series with only a slight slowing of growth and a slight increase in the crookedness of the tubes. The 0.01 per cent revealed marked inhibition of germination and retardation of tube growth, whereas the 0.1 per cent was extremely toxic.

At 35°C. almost complete bursting of tubes resulted in the 0.1 per cent series, and much bursting was found also in the 0.01 per cent group. The 0.005 per cent series was, again, essentially like the control. In the higher concentrations the tubes showed the characteristic shortness and crookedness that colchicine was invariably observed to evoke in this pollen. Because no bursting of tubes occurred at 15°C. or 20°C., it is evident that the effect of the drug is somewhat enhanced by the higher temperature.

In order to determine whether colchicine might show favorable stimulatory effects at a higher dilution, a series of pollen was grown in 0.001 per cent (1:100,000) colchicine at 25°C. Measurements of this series revealed no departures from the control.

A recent paper by Beck and Joly (1941) mentions some points which are in general accord with findings noted in the present paper, as well as with those in a previous report (Smith, 1939). These are as follows: (1) that "old" pollen shows less germination than fresh pollen; (2) that 3-indole acetic acid increases the germinative power of pollen; (3) that germination is enhanced by clumping of the grains and (4) that tubes have a tendency to grow outward and away from the cluster if artificial auxin is supplied to the growth medium.

Beck and Joly report bursting of tubes following enlargement of the tips of the tubes of the monocotyledonous pollen with which they work. Such a reaction was not observed at ordinary temperatures with any of the species used in the present study. In cultures of *Bryophyllum* and sweet pea which were buffered and adjusted to a pH scale extending from pH 3.5 to 9.5, however, a very high percentage of the tubes in the 3.5 and 9.5 cultures ceased elongation after attaining a length of about 50 microns and burst following the swelling of their tips into spheres. Inasmuch as iso-electric gelatin was used as a buffer and HCl and NH₄OH as adjusters, it seems probable that the swelling and bursting was due to the unfavorable pH and not to the toxicity of these substances.

SUMMARY

Studies of the germination of pollen of *Antirrhinum majus* and *Bryophyllum Daegremontianum* were designed to show the effects of the addition of 3-indole acetic acid, 3-indole butyric acid, naphthalene acetic acid, vitamin B₁ and colchicine to the culture medium. The effects of different temperatures on these cultures were investigated by the sugar-agar technique.

The use of pollen from a single flower for the inoculation of the cultures of the various test substances was found to be essential to studies of the pollen of these species. This procedure eliminated the variability resulting from differences in the physiological age of the pollen of different flowers.

The pollen of all species studied showed an increase in diameter of the tubes corresponding to an increase in the temperature of the environment. Snapdragon pollen showed (1) negligible growth at 15°C., (2) optimum germination and length of tubes at 25°C., (3) pronounced broadening and bloating of the distal portions of the tubes at 30°C., and (4) extensive bursting of the bloated tubes at 35°C. *Bryophyllum* pollen showed (1) marked growth at 15°C. and (2) optimum germination and length of tubes at 25°C. At 35°C. a great diversity of tube lengths resulted with many short, broad tubes and some extremely long ones with broadened proximal portions.

The auxins were favorable additions to the culture medium with only moderate stimulation in the case of snapdragon, whereas much greater stimulation of both germination and tube elongation was obtained in *Bryophyllum*. The greatest auxin stimulation occurred at 25°C., which was also the optimum temperature for growth of the pollen of these species. Three-indole acetic and 3-indole butyric acids were more effective stimulants than naphthalene acetic acid. Concentrations of auxins weaker than 1:50,000 were favorably stimulative. All stronger concentrations were toxic as indicated by decreased germination, bursting and distortion of tubes.

Evidence of favorable stimulation by the addition of vitamin B₁ was not found. The slightly greater tube width occurring in this medium is attributed to the increase in acidity resulting from the addition of the vitamin.

Colchicine was depressive to both germination and tube elongation at all temperatures used. In a highly dilute solution (1:100,000) the growth responses approached the condition found in the control. At temperatures of 25°C. and above, broadening and rupturing of the tubes were much more prominent than in the control series. Below 25°C. no bursting of the tubes was found.

The pollen of snapdragon manifests the peculiar response of bloating of the tubes to the following factors which are unfavorable to its growth: (1) temperatures of 30°C. or more, (2) the presence of colchicine in the culture medium, (3) high acidity and (4) "old" pollen, i.e., pollen from flowers that have dehisced several hours previous to inoculation.

ACCUMULATION OF NICOTINE IN RECIPROCAL GRAFTS OF TOMATO AND TOBACCO ¹

Ray F. Dawson

SINCE THE discovery of the general nature of nicotine by Pinner (1893) considerable interest has centered about the origin and the physiological functions of this alkaloid in the tobacco plant. The problem at present, however, is far from a satisfactory solution, principally because of the failure of the usual methods of experimental manipulation to influence the nicotine synthetic mechanism in a consistent manner. Indeed, Mothes (1928) has commented upon both the extreme stability of nicotine metabolism in the plant and the great difficulty to be encountered in any attempt to alter its course.

Heretofore, investigations dealing with the origin of nicotine appear to have been predicated almost entirely upon the assumption that the tobacco leaf is the principal seat of nicotine formation. The common observation that the leaf usually contains a greater proportion of nicotine than either root or stem provides a reasonable basis for such a view. An examination of the literature, however, has revealed facts which seem to be irreconcilable with this view. In the first place, the nicotine content of tobacco leaves appears to bear no constant relationship to size, growth, or to any other obvious characteristic, either morphogenetic or physiological, of the leaf (Mothes, 1928). Secondly, although tobacco leaves and shoots in various stages of development have been removed from the roots and cultured under a wide variety of conditions (Vickery, *et al.*, 1937; Mothes, 1928; Dawson, 1940), only in isolated and rather unusual cases has there been an apparent increase in the nicotine content of the detached aerial parts of the plant. It should, perhaps, be remarked in this connection that leaves and shoots in various

stages of development have been employed in these experiments with the result that the nicotine synthesizing capacity of young growing tissues as well as of fully matured tissues appears to have been rather fully explored.²

An obvious implication of these findings is that nicotine may not be produced in the aerial portions of the plant at all. Rather, if some connection between root and shoot is necessary for the continued accumulation of the alkaloid in stems and leaves, the possibility must be considered that nicotine (or its immediate progenitor) may be produced largely or perhaps solely in the roots. The present study was designed to follow the accumulation of nicotine in the aerial portions of tobacco plants when they are cultured outside the sphere of influence of tobacco roots and to investigate the ability of tobacco roots to donate nicotine to the aerial portions of another species of plant to which they may be grafted.

METHODS.—Plants of *Nicotiana tabacum* L. var. Turkish and of *Lycopersicum esculentum* Mill. var. John Baer were grown from seed in pots of white quartz sand to which were added daily applications of a mineral nutrient solution (Shive and Robbins, 1938). When the stems of both plants had reached a diameter of approximately three-eighths of an inch at the base they were severed at a point twelve inches from the roots and split to receive the scions. From the tobacco shoots thus removed the terminal four inches including the apical meristem were excised to serve as scions upon the tomato stocks. The tomato scions were secured from the older and more stocky

² Attempts in this laboratory to obtain nicotine from the lateral shoots which form on tobacco stalks during culture in moist chambers have been fruitless. Likewise, it has been impossible to detect nicotine in the callous tissue which forms over the basal ends of tobacco stalk segments during culture under the same conditions.

¹ Received for publication August 11, 1941.

The author is indebted to Professor C. M. Tucker for proof-reading the manuscript and to his sister, Martha, for technical assistance in the laboratory.

portions of the stems and contained one lateral bud each. The majority of the graft unions were of the cleft type, but a few approach grafts were also made. One-half of the tobacco and tomato stocks were stripped of their leaves at the beginning of the experiment. These are designated herein as leafy and leafless stocks, respectively.

The samples of leaf, stem, and fruit tissue were ground through a food chopper and then extracted with boiling water which had been acidified with dilute sulphuric acid. Nicotine was determined upon aliquots of these extracts by a method which has been described elsewhere (Dawson, 1939). In this method the total volatile bases including nicotine are removed from triplicate samples by simultaneous steam distillation. The distillates after titration are redistilled under reduced pressure at 40° C. By this procedure ammonia and the low-boiling amines are quantitatively removed and estimated by titration. Nicotine is calculated by the difference between the two titrations. Nicotine was isolated from some of the extracts as the dipicrate in order to furnish qualitative evidence for the presence of the alkaloid.

Because of the impracticability of performing large numbers of grafting operations the size of the samples selected for analysis was necessarily small (usually four plants). In some measure this objection has been met by collecting several such samples at intervals over a considerable period of time. However, the quantitative aspect of the data can assume only approximate significance, and the qualitative relationships are to be emphasized.

The data included in this paper represent the results of two separate experiments which were conducted during the early spring and the summer of

1941. The second experiment as regards both methods and results was essentially a duplication of the first, although larger numbers of grafts were prepared and only one sample was taken for analysis.

EXPERIMENTAL RESULTS.—Nicotine in tobacco scions upon tomato stocks.—The average nicotine content of one original tobacco scion at the time of preparation of the grafts was 1.3 mgm. (table 1). After thirty-one days of development upon tomato stocks, at which time increase in length of stems had been threefold and a total of ten new leaves had been produced upon each scion, the nicotine content per scion was 3 mgm. At the end of another twenty-eight days the scions contained an average of thirty-eight leaves each and had reached a stem length of approximately thirty inches. At this time the nicotine content per scion was only 4.1 mgm. Such slight increases are somewhere near the order of magnitude of experimental error and may be considered as indicating no change at all in total nicotine content until such time as the validity of the apparent change may become established by further experimentation.

Subdivision of the third collection of tobacco scions into three parts yielded some evidence concerning the fate of the nicotine in the original scion. The basal ten to eleven inches of each scion contained the entire quantity of nicotine (4.1 mgm.) which had been present in the beginning. The central portions of the scions up to the inflorescences contained no traces of nicotine, although this fraction represented 57 per cent of the sample in terms of fresh weight. The inflorescence of each scion, which contained buds, flowers, and pods in nearly all stages of maturity, was found to possess an average high-boiling base content of 1.3 mgm. (calculated as nicotine).

TABLE 1. Nicotine content and fresh weights of reciprocal grafts of tobacco and tomato. The values for fresh weight and nicotine content are expressed in terms of the average number of grams or of milligrams in one individual stock, scion, or fruit.

Sample	March 11		April 11	May 9		June 3	
	Weight gm.	Nicotine mgm.	Nicotine mgm.	Weight gm.	Nicotine mgm.	Weight gm.	Nicotine mgm.
Tobacco scions on leafless tomato stocks.....	3.7	1.3	3.0

Leaves of tobacco stocks.....	...	23.6	296.5	74.5	229.9	55.0	194.0

^a These values include stems as well as leaves.

^b Values not included in the calculation of the total nicotine content of the scions due to failure of the picrates to behave as nicotine dipicrate.

Positive identification of this volatile fraction as nicotine, however, was not made. It seems possible that this minute amount of material may have been composed of other high-boiling amines than nicotine (*cf.* Klein and Steiner, 1928).

Twenty-five days after the preceding collection a fourth sample of four plants was obtained, which presented a slightly different distribution of nicotine. The lower six leaves from each scion contained only 2.5 mgm. of nicotine, while none at all was found in the remaining forty-two leaves. In each stem, however, 6.1 mgm. of nicotine were found. The analytical data indicated the presence in the inflorescences of 17.6 mgm. of a high-boiling base which did not appear to be nicotine, since attempts to prepare the pieric acid derivative yielded only a yellow oil which could not be induced to crystallize.

The presence or absence of leaves on the tomato stocks did not seem to affect the total nicotine content of the tobacco scions (table 1). The rates of formation of the graft unions and subsequent growth of the tobacco scions, however, were appreciably increased in their presence. Analyses performed upon the tissues of the tomato stocks indicated that no nicotine had been translocated out of the scions.

The data from the second set of experiments are found in table 2. It will be noted that a 24-fold increase in the fresh weight of one tobacco scion during its development upon tomato roots was accompanied by an apparent net increase of only 0.6 mgm. of nicotine, a quantity entirely incommensurate with that which would be expected to obtain in a normal tobacco plant.

TABLE 2. Nicotine content and fresh weights of reciprocal grafts of tobacco and tomato from second experiment. The values for fresh weight and nicotine content are expressed in terms of the average number of grams or milligrams in one individual scion or shoot.

Date	Sample	Fresh weight	Nicotine
		gm.	mgm.
June 9	Original tobacco scions (9 in sample)	1.23	1.73
July 14	Tobacco scions on tomato stocks (20 scions in sample)	30.3	2.3
	Tomato scions on leafless tobacco stocks (15 scions in sample)	11.8	15.2
	Tobacco shoots from plants which had been decapitated at the time of preparation of the grafts. (Ten shoots in sample)	29.2	21.2

From the evidence at hand it cannot be stated unequivocally that the tobacco scions did not manufacture at least small amounts of nicotine. Inspection of the values in table 1 reveals that the nicotine content of the tobacco scions upon tomato stocks increased slowly but regularly throughout the period of culture. If this synthesis was actual and not the

result of sampling error or of an error in the analyses, then it raises an interesting question as to the kind of cell which in the stem or leaf can synthesize the pyridine and pyrrolidine ring structures of nicotine. In any event, it is quite apparent that the tobacco scions did not synthesize appreciable quantities of the alkaloid.

Nicotine in tomato scions upon tobacco stocks.—The distribution of nicotine between stock and scion in grafts of this type was in certain respects the reverse of that previously discussed for the reciprocal type. In the beginning there was, of course, no nicotine present in the tomato scions. The leaves of each of the tobacco stocks contained an average of 24 mgm. of nicotine. At the end of thirty-one days (table 1) the average tomato scion on the leafless tobacco stock had grown to a height of approximately fourteen inches while similar scions on the leafy tobacco stocks had grown an average of twenty inches in length. Analyses for nicotine indicated the presence in the tomato scions on the leafless tobacco stocks of an average of 37.6 mgm. of nicotine per scion and in the tomato scions on the leafy tobacco stocks of an average of 55.5 mgm. of nicotine per scion. The identity of the nicotine present in these tomato tissues was established by direct isolation.³ At the end of fifty-nine days of growth the tomato scions on the leafy and leafless tobacco stocks contained 258.3 and 135 mgm. of nicotine,⁴ respectively.

The influence of the leafy stocks was evident in hastening the development of the graft union and subsequent growth of the scion, so that the increased nicotine content of these scions compared with that of the scions on the leafless stocks is not to be considered unusual.

Changes in the nicotine content of the tobacco leaves on the leafy tobacco stocks were also of interest. In thirty-one days the quantity of nicotine present in these leaves had increased from 24 to 297 mgm. Such a change is to be expected as a result of the decapitation of the plant (Garner, *et al.*, 1934). The decreases to 230 mgm. and to 194 mgm. which occurred at the end of fifty-nine days and of eighty-four days, respectively, present a slightly different problem. If this decrease represents a loss by translocation or by volatilization, then such results are in conflict with those already discussed in connection with the fate of the nicotine in the tobacco scions on tomato stocks. It is necessary to note, however, that the leaves involved in this sample were all basal leaves most of which were so old that the chlorophyll had disappeared from the areas between the veins, and browning was evident along the leaf edges. A loss of nicotine from these leaves, therefore, may have represented simply a normal consequence of senescence (Vickery, *et al.*, 1935).

³ Eighty mgm. of nicotine dipicrate were isolated from 75 mls. of the hot water extract, a yield of 62 per cent of the theoretical. The crystals after recrystallization from boiling water decomposed at 224–225°C. (corr.). A mixture of these crystals with those of pure nicotine dipicrate yielded no depression in the decomposition point.

⁴ Decomposition point of the isolated dipicrate derivative was 224–225°C. (corr.).

The stems of the scions contained an average of 10 mgm. each of nicotine. Compared with the relative distribution of nicotine in the shoots of field grown tobacco (Vickery, *et al.*, 1935) the distribution of the alkaloid in the tomato scions of this experiment is quite similar and suggests that the same fundamental processes of nicotine synthesis and accumulation may prevail in each case. If so, this would seem to provide ample justification for the use of graft hybrids in the present study.

Flowering in the tomato scions was profuse and a rather large number of fruits were developed. Interest attendant upon the possibility of the occurrence of nicotine in the fruits led to an examination of the macerated whole fruit tissues by the methods already described. Nine green fruits ranging in size from 4 to 30 mm. diameter were found by quantitative analysis to contain a total of 6.4 mgm. of nicotine, or an average of 0.7 mgm. of the alkaloid per fruit. In terms of percentage of fresh weight these figures represent a nicotine content of 0.02, a value which is close to the limits of error of the methods employed. In order to substantiate these results, therefore, 125 mls. of the 165 mls. total volume of the fruit extract were subjected to steam distillation, and the alkaline distillate extracted with ether. Upon evaporation of the ether the characteristic pungent odor of nicotine was detected, and when added to two mls. of a saturated aqueous solution of picric acid a definite precipitate of nicotine dipicrate was formed. This precipitate was filtered off on a micro funnel and recrystallized from two mls. of hot water. The crystals were thrown down with a semi-micro centrifuge, and the supernatant fluid removed with a glass capillary by slight suction. A drop of alcohol was added to remove the excess picric acid, the alcohol was removed by suction, and the crystals were dried. The decomposition point of the material so obtained was 223–224°C. (corr.). It appears, therefore, that some of the nicotine must have been translocated to the tomato fruits, although the order of magnitude of such transport was extremely small.

Twenty-five days after the preceding collection a fourth sample of four plants was obtained. The tomato scions were rather large and bore a substantial number of fruits. The individual scions from the leafless tobacco stocks carried 1.3 mgm. of nicotine in the one ripe fruit and 5.4 mgm. in the nine green ones. The leaves and stems contained 500.7 mgm. of the alkaloid. The aqueous extracts of these latter tissues were combined and exhaustively distilled with steam after the addition of sodium hydroxide to alkalinity. The distillate was evaporated and the residues extracted with ether. From the ether extract 4.70 grams of crude nicotine dipicrate⁵ were obtained, a yield of 93.4 per cent of the theoretical.

From the leafy tobacco stocks four tomato scions were removed at the same time and examined for nicotine. Each scion bore one ripe fruit which con-

tained on the average 1.5 mgm. of nicotine and ten green fruits which contained a total of 35 mgm. The leaves and stems of the scions contained an average of 571 mgm. each, while each tobacco stock had accumulated a total of 194 mgm. of the alkaloid in the leaves.

One observation of a qualitative nature appears to be of some interest. Soon after the development of the first leaves on the tomato scions the edges of the leaflets developed a dry brown necrosis which was sharply set off from the normal green tissue. Whether there was a causal relationship between nicotine and this injury is not known, but for reasons which are given below there seems to be a good possibility that such was the case.

In a repetitive experiment quantities of nicotine accumulated in the tomato scions which were approximately 70 per cent as great as the quantities which accumulated in the lateral shoots of tobacco plants which had been decapitated and defoliated at the time of preparation of the tobacco and tomato grafts. Examination of the data in table 2, however, indicates that a direct comparison between the amounts of nicotine which accumulated in the tomato scions and in the intact tobacco shoots at the same stage of development were not of much value. The reason for this appears to be that differences in leaf shape and area and differences in photosynthetic efficiency resulted in differences in the quantities of foodstuffs delivered to the roots, the control and estimation of which would have been quite difficult if not impossible. It has been obvious throughout these experiments that the production of nicotine by the roots is profoundly influenced by the photosynthetic capacity of the tops.

Nicotine in approach grafts of tomato upon tobacco.—All the foregoing data were obtained upon cleft grafts. Two plants consisting of tomato scions upon tobacco stocks were obtained by the method of approach grafting. In principle it would appear that the movement of materials across such a graft union would involve some degree of lateral transport. That this actually occurred is indicated by the following data. After sixty-six days of growth the two scions weighed 129 grams dry. Both scions bore at this time 120 gm. of fruit (fresh weight). The tomato scions contained 382 mgm. of nicotine each, while the leaves on each tobacco stock contained 36 mgm. of nicotine.

Downward movement of nicotine in tomato scions.—One plant of tomato was decapitated and the tip of the cut stem grafted into the stem of an intact tobacco plant. After the union had occurred, the tobacco stock was allowed to develop a lateral shoot with the idea in mind that some of the food material necessary for the development of the tomato shoot might be translocated down the tomato stock from the tobacco plant and thence up the tomato shoot. If such translocation did occur, nicotine did not appear to be among the materials so transported, since no traces of the alkaloid could be found in the leaves of the tomato stock or of the tomato shoot.

⁵ The once-recrystallized material softened at 221°C. and decomposed at 225°C. (corr.). A mixture of this preparation with a sample of pure nicotine dipicrate yielded no depression in the decomposition point.

TABLE 3. *Nicotine content and fresh weights of approach grafts of tomato and tobacco. Grafts prepared June 9, 1941, and harvested July 19, 1941. The values for fresh weight and for nicotine content are expressed in terms of the average number of grams or of milligrams in one individual "stock" or scion.*

Sample	Fresh weight	Nicotine
	gm.	mgm.
"Leafless" tobacco grafts:		
Tobacco "stock"	19.4	4.5
Tomato stem	99.0	7.8
Seven leaves from sector of tomato stem immediately above insertion of tobacco "stock"	39.5	69.0
Remainder of leaves on tomato stem (17.5 per plant)	88.0	13.2
"Leafy" tobacco grafts:		
Tobacco "stock"	62.0	192.8
Tomato stem	112.0	3.4
Ten tomato leaves from sector of tomato stem immediately above insertion of tobacco "stock"	26.4	15.8
Remainder of leaves on tomato stem (22 per plant)	102.0	10.0

Unilateral movement of nicotine in tomato scions.

—Eight tobacco plants were similarly decapitated and grafted into the sides of the stems of eight tomato plants. Four of the tobacco plants were defoliated. Union of the grafts occurred readily, and the tomatoes grew normally for some time. It was eventually noticed, however, that the same leaf injury, which had been noted in all cases in which nicotine had accumulated in tomato leaves, also occurred in grafts of this type. Certain aspects of the distribution of the injury, however, seemed significant. First, only the tomato plants which were grafted to the leafless tobacco "stocks" acquired the characteristic browning and necrosis of the leaflet edges. Those which were grafted to the leafy tobacco "stocks" were entirely free from injury. Secondly, only the leaves on that longitudinal sector of the stem which was directly above the graft union were damaged. The remainder of the leaves on the tomato stems were apparently perfectly normal.

The above behavior was correlated with similar changes in the nicotine content of the tomato leaves. In the leafless tobacco grafts 84 per cent of the total amount of nicotine in the leaves of all the tomato scions was found in the twenty-nine leaves which were located in the sector of the stems immediately above the points of insertion of the tobacco "stocks." The remaining 16 per cent of the alkaloid was found in those seventy tomato leaves which were located in all other sectors of the tomato stems. The tobacco stocks as well as the tomato stems contained only small amounts of the alkaloid. On the other hand, in the leafy tobacco grafts the great bulk of the nicotine was not located in the tomato scions at all but was found in the leaves of the tobacco "stocks." Of the quantity of nicotine which did find its way to the to-

mato scions in these grafts, approximately 61 per cent was located in the ten leaves in the stem sector immediately above the graft union, while the remainder was found in the remaining sixty-five leaves on all other sides of the stems (table 3).

Such data seem to provide an almost irrefutable argument for the translocatory origin of nicotine in the leaves of these graft hybrids. The path of transport is entirely unknown. Since movement seems to be upward in all cases and never down, it is tempting to suggest that the nicotine may be translocated in the xylem and that nicotine is not normally found in any other tissues of the stem in any appreciable quantities. Experiments are at present under way in which the nicotine content of the various tissues of the tobacco stem will be determined after they have been separated from one another by dissection. The accumulation of such large quantities of nicotine in the leaves of the tobacco "stocks" rather than in the leaves of the tomato "scions" in the latter type of graft may best be explained by assuming that the larger photosynthetic area exposed by the leafy as compared with the leafless "stocks" made it possible for the tobacco roots in the former case to synthesize much more nicotine than would otherwise have been possible. As the nicotine was then translocated up the stem it tended to accumulate mostly in the tobacco leaves rather than in the tomato "scion" which was probably supplied in large part by its own root system. The failure of the nicotine to induce visible injury in the tomato leaves above the graft union in the leafy tobacco grafts was obviously due (table 3) to its low concentration.

DISCUSSION.—From the foregoing it is clear that nicotine accumulates only in those graft hybrids which possess a tobacco root system. Furthermore, the alkaloid does not appear, in appreciable quantities at least, in graft hybrids, the tobacco component of which is the aerial shoot.⁶ The significance of these observations appears to lie principally in the fact that *nicotine (or its progenitor) was synthesized in the tobacco roots and translocated to the tomato leaves, and that it was not synthesized in appreciable quantities in the tobacco leaves.*

It has been possible to induce growth in tobacco leaves and stems without either the presence or the resulting synthesis of nicotine. This is in direct contrast to the conclusions of Mothes (1938), who worked with intact tobacco plants; but it does not invalidate his data, for they actually become more susceptible of interpretation when the nicotine content of a leaf is viewed not as a result of synthesis *in situ* but as a result of translocation.

During the growth of the tobacco scions the nicotine which was present in the original scions at the time of preparing the grafts remained in the lower portions of these scions and was not translocated to other parts of the plant. Thus the new growth which

⁶ Similar results have been obtained at the Experimental Institute Leonardo Angeloni for tobacco cultivation at Scafati (Naples) according to a news item reported by Raffaele Sansone in the News Edition of Industrial and Engineering Chemistry for March 20, 1939.

appeared was entirely nicotine free. The absence of translocation outward once the nicotine has made its appearance in the leaf is in complete accord with the results of Mothes. There was no indication that nicotine was either used up by the metabolic processes of the leaf or lost from the leaf by volatilization. The former possibility has also been eliminated by Mothes. The second possibility has, however, been supported by Chazé (1931) in connection with the fate of nicotine in the intact tobacco plant. The present data do not seem to substantiate the view of Chazé.

The distribution of nicotine between stem and leaf in the tomato scions was quite similar to that which occurs in the intact tobacco plant. That is, the stems remained relatively low in nicotine content, while the amount of alkaloid in the leaves increased to a comparatively high value. This point together with the observation that nicotine accumulated unilaterally in those tomato plants which had been grafted laterally to tobacco stocks appears to complete the evidence for the translocatory nature of the origin of the alkaloid in the leaves.

A question arises at this point, however, with regard to whether nicotine was translocated as such or as some precursor or intermediate which might have been converted directly to the alkaloid once it had been deposited in the leaf cells. Definite evidence for one or the other of these possibilities must await the completion of experiments in which the various tissues of the stem are to be separated from one another and analyzed for nicotine. If the first alternative is the correct one, then nicotine should be found in appreciable amounts in either the xylem or the phloem. If the latter alternative is more nearly true, the nicotine of the stem should be found only in the living cells of the cortex or pith or in the cambium.⁷

If the events which have just been described can be taken as indications of the actual behavior of nicotine not only in the reciprocal grafts between tobacco and tomato but also in the intact tobacco plant, many of the apparently contradictory data which are re-

⁷ Since the manuscript was submitted, nicotine has been isolated as the dipicrate in good yield from the xylem of tobacco stalks and also from the sap which bleeds from the xylem of cut stumps of tobacco stalks. The complete data from these experiments will appear elsewhere.

corded in the literature regarding the alkaloidal content of the leaves may be reconciled. It would then appear that nicotine is synthesized in the tobacco root and that it is translocated through the stalk to the leaf where it accumulates. The nicotine content of the tobacco leaf would thus be determined by the net effect of a number of variables some of which would be (1) the size, age, and activity of the root system, (2) the relative size of the shoot, and (3) the total amount of organic carbon and of inorganic nitrogen supplied to the roots by the aerial portion of the plant and the soil, respectively. Whether such relationships actually occur must be established by more direct experimentation. Investigations are now in progress in this laboratory in which the nicotine synthetic capacity of excised tobacco roots in sterile culture is receiving some consideration.

SUMMARY

The distribution of nicotine between stock and scion in reciprocal grafts of tobacco and tomato has been studied.

When tobacco scions were grown upon tomato stocks no appreciable accumulation of nicotine occurred in the tobacco leaves or stems. In fact, the nicotine which was originally present in the scion remained in the lower leaves and stem, and the leaves and stem tissues which subsequently developed were nicotine free.

When tomato scions were grown upon tobacco stocks nicotine was found in small quantities in the tomato stems and fruits, and large quantities of the alkaloid accumulated in the leaves. Nicotine accumulation in the leaves of tomato shoots was sectoral when tobacco stems were decapitated and inserted into the tomato stems unilaterally.

Growth, including both mitosis and cell enlargement, occurred quite normally in the absence of detectable amounts of nicotine when tobacco shoots were grafted upon tomato stocks. It appears, therefore, that nicotine, in appreciable quantities at least, is not essential for the development of the aerial portions of the tobacco plant.

RELATION OF SEED WEIGHT TO VEGETATIVE GROWTH, DIFFERENTIATION, AND YIELD IN PLANTS¹

Stanley W. Oexemann

For a period of approximately three hundred years plant propagators have worked with methods for separating seeds into classes, according to weight (Yokoi, 1903). During the past century many investigations have been made on the subject, most of the papers appearing during the last fifty years, prior to 1930. Certain investigators (Schmidt, 1924; Cummings, 1914; Kiesselbach, 1924; Delassus, 1911) have reported results indicating that plants produced from heavier seeds show more vigorous growth, attain greater weight and size, and produce larger yields as determined by number and size of fruits than do plants grown from seeds of lighter weight. On the other hand others have shown by the results of their experiments that the seed weight factor is significant with respect to size of plants only during the early stages of plant growth, and that, if the growing season is long enough, the early superiority might disappear entirely (Golinska, 1929; Kotowski, 1929; Rohmeder, 1939; Vanselow, 1933).

This paper describes studies made to determine the relation of the initial dry weight of seeds to subsequent plant growth. The weights of the seeds were correlated with growth in stem length, leaf areas, dry weight of roots and tops, number of leaves, number of buds, number of flowers, and to fruit and seed yield. Studies were also made on tissue development in stems, leaves, roots, and petioles.

EXPERIMENTAL METHODS AND MATERIALS.—Seeds of each of the following were used in these experiments: Soybeans (*Soja max* Piper, var. Biloxi and Mandarin), cucumber (*Cucumis sativus* L., var. Early White Spine), and tomato (*Lycopersicon esculentum* Mill., var. Bonny Best). The plants were grown in the University of Illinois botany greenhouses.

The seeds of soybeans and cucumber were placed into three groups, designated by the letters X, Y, Z, and the seed coats were removed. In the seeds designated by the letter X, none of the food storage tissue was removed; from those seeds designated by the letter Y, approximately half of one cotyledon was severed; and from those seeds designated by the letter Z, one whole cotyledon was cut off. In other words, the seeds in set Y and in set Z contained approximately three-fourths and one-half respectively of the amount of food reserve contained within the seeds of set X. The seeds were then weighed accurately to one-tenth of a milligram and planted in sterilized well mixed loam soil. The pots containing the seeds were watered daily with sterile tap water until the epicotyls had appeared above the surface of the soil. From this time on these plants were watered daily with unsterilized tap water.

¹ Received for publication August 11, 1941.

This work was carried out under the direction of Doctor Harry J. Fuller in the Department of Botany of the University of Illinois.

The method for reducing the amount of reserve food material in seeds, as described above, was not used with the tomato because it is difficult to carry out on small seeds. The tomato seeds were planted in sawdust flats and as soon after germination as the cotyledons appeared above the sawdust, cotyledonary tissue was removed as follows: The seedlings of one group, designated as group X, were left whole; one-half of one cotyledon was removed from each of the seedlings of group Y; each of the seedlings of group Z had a whole cotyledon removed. Twenty-four hours later the plants were carefully taken from the flats, washed in tap water, and after the superficial water had been removed with blotting paper, were weighed accurately to one-tenth of a milligram. The flats were kept in the dark from the time the seeds were planted until the seedlings were removed except for a few minutes during which time the cotyledons were cut. The seeds and seedlings were adjusted to oven dry weight by calculation after percentage weight loss had been determined by drying representative samples in an oven at 100°C., until no further decrease in weight occurred. The tomato seedlings were planted in well mixed loam soil and were watered with unsterilized tap water.

Cultural conditions, temperature, light and moisture were controlled and equalized for all plants as far as possible. All plants were grown in 4½-inch pots, except that tomato and cucumber plants used for yield determinations were grown in eight-inch pots. Each plant was labeled to indicate its group and the weight of the seed from which it grew. Corresponding records were made on data charts.

Dry weights of plants or plant parts were determined by placing these into open weighing bottles and drying them in an oven at a temperature of 100°C., until they showed no further loss in weight. The bottles were then closed and after cooling, the plants or plant parts together with the bottles were accurately weighed to one-tenth of a milligram. Corrections for weights of the bottles were made later.

Leaf areas were determined by making outlines of the leaves on paper having thirty-six squares per square inch. The number of squares was determined by means of a calculator, and the value of these was then converted into square centimeters.

Measurements of cross-sections of roots, stems, petioles, leaves, and their respective tissues were made from permanent mounts on slides by means of calibrated ocular micrometers. Tissues, from which sections were made, were taken at comparable measured positions on each plant so as to avoid errors due to positional differences of the tissues. All sections were made from tissues embedded in paraffin.

Correlation coefficients were determined from the formula:

$$C = \frac{S_{xy}}{\sqrt{(Sx^2)(Sy^2)}}$$

in which C represents the correlation coefficient; S the sum of the respective factor or factors; x the deviations of the seed weights or in the tomato the deviations of the seedling weight from the average; y the deviations of the numbers of flowers, buds, leaves, fruits and seeds, weights of various portions of the plants, growth rates, order of ripening of organs or fruit, and other growth criteria from their respective averages. A coefficient between 0 and plus 1 indicates a positive correlation; a value between 0 and minus 1 indicates a negative correlation. In this paper a negative correlation is indicated by a minus sign; a positive correlation by no sign.

RESULTS AND DISCUSSION.—The life cycle of a plant can be divided into two more or less distinct

phases: The first is the vegetative phase in which the plant undergoes extensive vegetative development; the second phase involves the reproductive processes. It was recently emphasized that the reproductive activities of flowering plants consist of two related but physiologically very different phases: flowering and fruiting (Loehwing, 1938).

Correlation coefficients for numbers and weights of plant organs.—One hundred fifty plants were used for each species or variety in making correlation determinations between seed weight and numbers and dry weights of plant organs. The data recorded were taken at the end of the vegetative phase of plant growth as a few flowers made their appearance. The correlation values indicate that there still

is a fair correlation between seed weight and number and size of plant organs at the beginning of the flowering phase of the growth cycle (table 1).

The correlation between seed weight and number of flowers may be interpreted as a correlation between seed weight and time of flowering rather than between seed weight and number of flowers produced. This is because at this stage of the growth cycle only a few (the earliest flowers) are open.

A higher correlation value exists between seed weight and dry weight of tops than between seed weight and dry weight of roots. When the plant is taken as a whole, *i.e.*, top and root together, the correlation value usually lies somewhere between that obtained when the top and the root are considered separately.

Leaf areas and cross-sectional dimensions of vegetative organs.—Ninety plants of each species or variety were used. Cross-sections of the leaves were made 5 mm. above the basal attachment of the blade to the petiole. Petiole cross-sections were made 2 cm. above the base of the petiole. The cross-sections of the stem were made 2 cm. above the second node, and root cross-sections were taken 1 cm. below the collar.

A fairly close relationship exists between seed weight and leaf areas and, except in the case of the tomato, between seed weight and cross-sectional dimensions of vegetative organs as shown by the correlation values (table 2).

Growth rate.—During early life, the embryo of a seed is dependent for its growth upon the food stored in the cotyledons or endosperm. This food is made

available for the embryo by digestion at an increasing rate as the seed germinates and the plant begins to grow. After the leaves unfold and begin to increase in size, photosynthetic activity supplements the storage food supply of the plant. As the plant increases in size, the growth rate also increases up to the initiation of flower primordia or the actual appearance of flowers. At this point the growth rate slows down considerably, partly because more and more of the nutritive supplies formerly used for vegetative growth are used for reproductive functions and partly because of alterations in the condition of growth-promoting and growth-inhibiting substances (McCollum, 1934).

Growth rate correlation coefficients were determined for the relationship between seed weight and weekly increases in stem elongation. Measurements were taken at semi-weekly intervals, but computations were made on a weekly basis. One hundred fifty plants were used for each species or variety (table 3).

During the first week of the growth period there is very little difference in the growth rate between the plants from the different seed weight groups. It has been stated that the metabolic translocations of reserve food material from the cotyledons to the growing plant is more efficient in the seedling containing the smaller amount of stored food (Gould,

values, beginning with the seventh week, progressively increase for a period of time, depending on the time required for the plants to reach maturity. Usually near the end of the growing period the values again swing toward the positive side (fig. 1-4; table 3). Golinska (1929) has pointed out that the length of the growth period and the speed of development of a plant are hereditary and cannot be influenced much by seed weight. Heredity thus seems to be responsible for the shift in correlation values during the sixth or seventh week of the growth period.

The values obtained by measurements made of total stem length at semi-weekly intervals were plot-

ted against time, giving sigmoid growth curves (fig. 5-8). The progress of these plants is more easily seen by plotting the average increment at semi-weekly intervals against time, thus giving graphic representations of the grand period of growth (fig. 1-4).

There seems to be little or no relationship between seed weight and height of plants at maturity. Plants from seeds of lighter weight may in some instances surpass in height the plants grown from heavier seeds (fig. 5-8). The early superiority of plants from heavier seeds over that of plants from lighter seeds gradually disappears, and, if the growing season is long enough, the early differences may disappear en-

tirely (Kotowski, 1929; Rohmeder, 1939; Vanselow, 1933).

At the termination of the experiments the growth period had not yet ended for the cucumber and the tomato (fig. 3, 4, 7, and 8). The reasons for not carrying these experiments to completion were: (1) These plants have a very long growth period under greenhouse conditions. (2) During the latter part of the period, the growth becomes rather irregular due to fruiting conditions and hereditary factors. (3) The work was carried out far enough to show the fundamentals involved, namely, that the plants from the lighter seeds have a slower initial growth rate, but that their growth rate later usually surpasses that of the plants from the heavier seeds.

The percentage of cotyledonary tissue removed from seeds appears to have a smaller effect on the early growth rate of a plant when the seeds are large than when they are smaller. There is also less effect when the true leaves come early in the development of the plant. In Biloxi soybeans which have relatively heavy seeds and a relatively early and proportionate development of photosynthetic surface, the effect on the growth rate by the removal of a certain percentage of storage tissue is relatively small. Mandarin soybeans have seeds of lighter weights and a smaller development of early photosynthetic surface; here the reduction of seed weight has a greater effect on the growth rate. Cucumbers have seeds of relatively light weight and a relatively late development of true leaves; here the effect produced by the removal of a certain percentage of storage tissue on the early growth is still greater than in Mandarin soybeans. The relation between the percentage of storage tissue removed from seeds and early plant growth appears to be dependent, therefore, on the initial weight of the seed and on the time and speed of development of photosynthetic surface.

Seed weight and tissue differentiation.—Thirty plants were used for each species or variety. Sections were made as noted above.

The results indicate that the reduction in size of various tissues and the decrease in number and size of vessel-like elements, due to the removal of different portions of reserve food tissues, is not proportional to the amount of such tissue removed, at least not beyond a certain point. In general there is a greater degree of difference in reduction between plants of group X and plants of group Y than between plants of group Y and plants of group Z (table 4).

There is a closer relationship between seed weight and actual cross-sectional areas of tissues than between seed weight and the relative development of the various tissues in a section (table 4). In other words, when reduction in tissue development occurs, the tissues are all reduced in approximately the same ratio; thus the percentage values remain more or less constant. In the percentage distribution of tissues, seed weight generally has the greatest effect on xylem development.

Except for vascular bundle number, which according to these experiments, in the species used, is nearly a constant and is not affected by seed weight, the results are in harmony with those reported in the literature (Delassus, 1913). Delassus found that in the plants with which he worked (beans, vetches, lupins) the vascular bundle number decreased with a decrease in reserve food in seeds from which the plants grew. This fact was not substantiated by the author's experiments.

Seed weight and yield.—There is considerable controversy as to whether larger and heavier seeds will produce plants with greater yielding capacities. Certain reports in the literature indicate that larger and heavier seeds produce plants which in general produce yields superior in dry weight, numbers of fruit, or in quality to those produced from lighter seeds (Fikry, 1936; Cummings, 1914; Staffeld, 1926). On the contrary other papers present results which show little or no relationship between seed weight and yield (Kotowski, 1929; Montgomery, 1908; Rotunno, 1924).

In the experiments reported here, ninety plants of each species or variety were used for yield determinations. The soybean fruits were harvested after the plants had dried naturally and the cucumber fruits at the end of ninety days. The tomato fruits were harvested as they ripened, beginning about the one hundred tenth day and ending about the one hundred sixtieth day. The tomatoes remaining on the vines after the sixth week of ripening were picked green. Dry weights and numbers of fruits and seeds were correlated with the dry weights of the seeds from which the plants were grown (tables 5 and 6).

All the correlation values are very low with two exceptions, both in Biloxi soybeans, these exceptions being in the correlation between: (1) seed weight and total average weight of seeds produced per plant, and (2) seed weight and individual average seed weight per plant. These exceptions do not seem to be significant, however, because: (1) they are but two in number; and (2) there seems to be little difference in yield between the plants originating from the heaviest seeds and those coming from the medium weight class. The difference seems to be in the yield produced by the plants from the lightest seed weight group. The correlation values between seed weight and order of tomato ripening are low, thus showing no relationship.

Seed weight in relation to mortality rate and disease resistance.—It has been reported in the literature that plants grown from heavier seeds seem to be less susceptible to rusts than plants grown from seeds of lighter weight (Norton, 1913; Delassus, 1911). Vanselow (1933) pointed out that plants from lighter weight seeds show a higher mortality rate. In the experiments reported in this paper, no study was made of the relation of disease resistance to seed weight, but it was observed that the mortality rate was higher among the plants from the lighter seeds as compared to the plants from the heavier seeds. In soybeans the percentage of mortality was

2 per cent in the plants from the heavy seeds (Biloxi 0.2466 g.; Mandarin 0.1472 g.), 3.5 per cent in plants from the medium weight seeds (Biloxi 0.1859 g.; Mandarin 0.1246 g.), and 11 per cent in the plants from the light seeds (Biloxi 0.1247 g.; Mandarin 0.0965 g.). Cucumber plants from heavy and medium weight seeds (0.0241 g. and 0.0180 g.) showed 3 per cent mortality as compared to 8 per cent mortality in plants from light seeds (0.0128 g.). In tomato there was a mortality of about 3 per cent with no noticeable relation to seed weight. The mortality rate, in all cases, reached its peak during the second or third week.

SUMMARY

It has been shown that there is a positive correlation between the initial seed weight and number, size, dry weight and cross-sectional dimensions of the various organs of the plants used in these experiments at the beginning of the flowering phase of the growth cycle. The values of such correlation vary among the different species and varieties of plants used in these experiments.

The importance of the seed weight factor is greatest during the early stages of plant growth. In tomatoes, cucumbers, and soybeans, the plants grown from the lighter seeds have a slower initial growth rate which persists till about the end of the sixth week; thus there is a positive correlation for this period of growth. Beginning with the seventh week and generally continuing to the end of the growth period, the growth rate for the plants grown from the lighter seeds exceeds that for the plants grown from the heavier seeds; thus the correlation values for this period are generally negative. Under favorable

greenhouse conditions the early superiority of plants grown from heavier seeds over those grown from lighter seeds is generally lost by the time the plants reach maturity.

The relation between the percentage of storage tissue removed from seeds and early plant growth seems to be dependent on the natural weight of seeds and on the time and speed of the development of photosynthetic surface.

The plant tissues (pith, xylem, and tissues outside the xylem) are all reduced in cross-sectional area in approximately the same ratio.

There appears to be a relation between seed weight and number and size of vessel-like elements. There is also a reduction between seed weight and vascular bundle size (length and width as seen in cross-section), but not between seed weight and vascular bundle number. Vascular bundle number varies with the species and thus seems to be a hereditary characteristic.

When the plants used in these experiments are grown under favorable greenhouse conditions, there is but little relation between seed weight and yield (numbers, sizes, and dry weights of fruits and seeds). No relationship was found between seed weight and order of fruit ripening in the tomato.

A higher mortality rate was found among seedlings grown from seeds of lighter weight than among seedlings grown from heavier seeds. This difference in mortality rate is probably due to differences in plant vigor and disease susceptibility.

STUDIES IN THE GENUS *SCIRPUS* L. IV. THE SECTION BOLBOSCHOENUS PALLA¹

Alan A. Beetle

THE LEAFY, perennial bulrushes comprising the section *Bolboschoenus*, subgenus *Euscirpus* (Beetle, 1940) of the genus *Scirpus* (Cyperaceae), are common in temperate regions of the Northern Hemisphere between latitudes 30° and 50°. Outside of this area they are rare except for a concentration in Australia. The six species and two varieties recognized here form a closely related group of extremely variable species. The universal tendency to confuse all entities with the Linnaean *S. maritimus* has obscured an accurate understanding of their ranges and affinities.

Inasmuch as the haploid number 55 has been reported for *Scirpus maritimus*, *S. paludosus*, *S. fluviatilis*, and *S. robustus*, it is presumed that this is not an aneuploid series as is the case in certain other sections of *Scirpus* (e.g., Section *Lacustres*). Reports of other numbers, all smaller, for these species are probably incorrect and due to the extreme technical difficulties involved.

The longevity and easy viability of *Scirpus* achenes lead inevitably to a wide distribution of the species. Thus the occurrence of odd distributional patterns or of occasional extra-limital localities should not be a cause for undue concern. *Scirpus robustus* occurs naturally all along the Atlantic coast of North America but suddenly reappears near the two largest west coast seaports at Long Beach and around San Francisco Bay. The Eurasian *S. tuberosus* occurs near both New York and New Orleans. Surely these localities represent introductions over shipping lanes.

The species listed here are of great importance in wild life conservation, the large and abundant achenes constituting an important bird food. The species may also be of some significance as soil binders on river estuaries or along the coast but are not otherwise of major economic importance.

In the preparation of this paper material in the herbaria of the following institutions has been consulted: Gray Herbarium (G), Harvard University; Rocky Mountain Herbarium (R.M.), University of Wyoming; University of California (U.C.); The Academy of Natural Sciences of Philadelphia; United States National Herbarium (U.S.); New York Botanical Garden (N.Y.); California Academy of Sciences; Dudley Herbarium, Stanford University; Field Museum (F.M.), Chicago; Missouri Botanical Garden (M.O.), St. Louis; and the author's personal collection. In the interest of brevity the source of sheets will not be further specified, except in the case of types.

TAXONOMIC TREATMENT.—Section *Bolboschoenus* Palla in Koch, Syn. Deutsch. Fl. 3: 2531. 1904. Perennials; joints of the rootstocks often enlarged into hard woody tubers; stems leafy; involucre of folia-

ceous bracts; spikelets terminal, sessile or umbellate; stamens 3; style 2- or 3-fid; achene trigonous, compressed, or lenticular, smooth under low magnification, gray or brown, apiculate; bristles usually present. (Type species: *Scirpus maritimus* L.)

Key to the Species

- Achenes lenticular; style 2-fid.
 - Spikelets 3 to many, often pedicellate. 1. *S. paludosus*
 - Spikelets 1-3, all sessile. 2. *S. strobilinus*
- Achenes compressed- to sharply trigonous; style 2- or 3-fid.
 - Leaf normally not over 6 mm. broad; secondary roots not conspicuous.
 - Style normally 2-fid; spikelets ovate-acute. 3. *S. maritimus*
 - Spikelets several.
 - Spikelets solitary. 3. *S. maritimus* forma *monostachyus*
 - Style normally 3-fid.
 - Spikelets oval. 4. *S. maritimus* var. *fernaldi*
 - Spikelets broadly cylindrical. 3. *S. maritimus* forma *macrostachyus*
 - Spikelets narrowly cylindrical, acute. 5. *S. tuberosus*
- Leaf commonly 8-10 mm. broad; secondary rootlets conspicuous.
 - Spikelets few, mostly sessile, or single on short rays. 6. *S. robustus*
 - Spikelets many, one to several on long rays.
 - Achenes dark brown, 3 mm. long. 7. *S. robustus* var. *novae-angliae*
 - Achenes dull gray-brown, 4 mm. long. 8. *S. fluviatilis*

1. *SCIRPUS PALUDOSUS* A. Nels.
 - Scirpus campestris* Britt. in Britt. & Brown, Ill. Fl. 1: 267. 1866; not Roth (1795).
 - Scirpus paludosus* A. Nels. Bull. Torrey Club 26: 5. 1899.
 - Scirpus robustus* var. *campestris* Fern. Rhodora 2: 241. 1900.
 - Scirpus robustus* var. *paludosus* Fern. op. cit. 1900.
 - Scirpus robustus* var. *compactus* Davy ex Jepson, Fl. W. Mid. Calif. 88. 1901.
 - Scirpus pacificus* Britt. ex Parish, Bull. South. Calif. Acad. Sci. 4: 132. 1905.
 - Scirpus interior* Britt., Man. Fl. N. U. S. ed. 2, 178, 1905.
 - Scirpus brittonianus* Piper, Cont. U. S. Nat. Herb. 11: 157. 1906.
 - Scirpus campestris* var. *paludosus* Fern., Rhodora 8: 162. 1906.
 - Scirpus maritimus* var. *paludosus* Kuenth. ex Fedde, Report. Spec. Nov. 23: 200. 1926.

Culms 0.5-1.5 m. tall, erect from smooth, brown, horizontal rhizomes, thickened at the nodes, frequently forming tubers; roots slightly spongy, the secondary roots inconspicuous; culms sheathed half their height, sharply trigonous, smooth; leaf sheaths

¹ Received for publication August 18, 1941.

green, the hyaline orifice abruptly truncate, the blades 3–5 cm. long, commonly 8 mm. broad, the margins and midrib scabrous at tip only; bracts of the inflorescence 2–5, leaf-like, unequal, the outer up to 2 cm. long, the others progressively shorter, the margins and midrib scabrous; inflorescence of 3 to many spikelets, 1–2.5 cm. long, 0.5 cm. broad, ovate to cylindric-acute, sessile or umbellate; primary rays up to 5 cm. long, smooth; scales ca. 6 mm. long, the midrib prolonged 2 mm. beyond the bifurcate apex, light brown, hairy; bristles 2–6, about half length of achene, fragile, minutely barbed; stamens 3, the style 2-fid, 6 mm. long; achenes very variable in size, 3–4 mm. long, 2 mm. broad, light to dark brown, ovate, lenticular, apiculate. April–August.

Type from Granger, Wyoming, *Aven Nelson* 3874 (R.M.).

Range: Fresh to strongly saline water; on the Atlantic Coast from New Brunswick to New Jersey, occasionally inland in Quebec and New York; from Saskatchewan south to Texas and west to the Pacific Coast, Hawaiian Islands, Argentina.

CANADA: Quebec: Magdalen Is., *Fernald et al.* 6981 & 6983 & 4459; Colchester Co., Truro, *Fernald & Wiegand* 4248; Vercheres Co., Varennes, *Victorin* 28,652; Rimouski Co., Rimouski, *Svenson & Fassett* 1004.

Nova Scotia: Hants Co., St. Croix River, *Prince & Atwood* 1024; Sable Island, *St. John* 1160; Shelburne Co., Jordan Falls, *Fernald & Long* 23,397.

HAWAIIAN ISLANDS: Island Oahu, Heller 2208, Mani. Degener 9027; Honolulu, Hitchcock 13808.

The strangely disrupted range of this species may explain in part some of the difficulty which has been experienced in attempting to treat it satisfactorily. The confusion lies principally in attempting to distinguish between *Scirpus maritimus* and *S. paludosus*. Fernald indicated that all the referable North American material must be segregated from the European, whereas Mackenzie, recognizing that true *Scirpus maritimus* occurred in North America, wished to relegate to that species all the collections of these two species from the northeastern coast. Both apparently overemphasized the principle of geographic isolation as a clue to speciation in closely related groups. Actually both *S. maritimus* and *S. paludosus* occur in this area. Although not easily distinguished they may be separated by a number of characters, including the shallowly bifurcate apex of the scale, the usually narrow leaves, and the compressed-trigonus achene of *S. maritimus* as opposed to the deeply bifurcate apex of the scale, the usually broader leaves, and the wholly lenticular achene of *S. paludosus*.

This species exhibits only moderate variation. In some areas the majority of the specimens appear to have light as opposed to dark brown scales (e.g., the Rocky Mountain region, although the type of *Scirpus paludosus* is not remarkable in this respect), in others the spikelets are frequently rayed instead of sessile (particularly along the Pacific coast), and again the swollen tubers on the roots may be mostly absent (New England). None of these represent varieties of the strength accepted by the author.

2. *SCIRPUS STROBILINUS* Roxb.

Scirpus strobilinus Roxb. Hort. Beng. 6. 1814, nomen nudum; Fl. Ind. ed. Carey & Wall. 1: 222. 1820.

Scirpus affinis Roth, Nov. Pl. Sp. 30. 1821.

Scirpus maritimus var. *affinis* Clarke in Hook. Fl. Brit. India 6: 659. 1894.

Scirpus balna Ham. ex Clarke op. cit. 1894, nomen in synonym.

Bolboschoenus affinis Drob. in Trav. Mus. Bot. Acad. Petersb. 16: 139. 1916.

Culms up to 5 dm. tall, erect from slender, smooth, horizontal rhizomes; roots often spongy, the secondary rootlets inconspicuous, the culms thickened at their base, sheathed to one-half their height, sharply trigonous, sometimes obscurely scabrous at the summit, leafy, the sheaths green, the orifice truncate, blades to 2 dm. long, 5 mm. or less broad, the margins scabrous near the tip; bracts of the inflorescence 1-3, unequal, the outer up to 1 dm. long, scabrous-mar-

gined; spikelets one to 5, usually not more than 3, sessile, 2 mm. long, 1 mm. broad, ovate, light brown, the scales 7 mm. long, 4 mm. broad, light brown, pubescent, mucronate from a bifurcate apex; bristles 3 to 6, fragile, shorter than the achene; style 2-fid; achene lenticular, dark brown, ovate, apiculate, 3 mm. long, 2 mm. broad. October.

Type from India, "ad ripas Gangia," presumably in the Herbarium of the Kew Botanical Gardens.

Range: India and Turkestan.

INDIA: Punjab, Drummond 24,934, Stewart 12,501 & 13,411; East Bengal, Herb. Griffith.

Roxburgh's original description of *Scirpus strobilinus*, although short, seems amply to justify the application of the name to this species. The complete diagnosis is as follows: "Sc. radice stolonifera, culmo trigono basi folioso, foliis triangularibus canaliculatis, spica laterali solitaria, involucri monophyllo, squamis cordatis cuspidatis, stigmatibus bifido, setis hypogynis senis glabris. Hab. ad ripas Gangia." Furthermore, this is not the first time that the name has been connected with this entity. C. B. Clarke (see synonymy listed above) at the time he proposed the combination *Scirpus maritimus* var. *affinis* listed *S. strobilinus* in the synonymy.

3. *SCIRPUS MARITIMUS* L.

Scirpus maritimus L. Sp. Pl. 1: 51. 1753.

Scirpus capensis Burm. f. Fl. Cap. Prod. 3. 1768.

Scirpus mucronatus Pollich. Hist. Pl. Palat. 1: 44. 1776-77.

Scirpus maritimus var. *compactus* Kroch, in Reich. Ic. Fl. Germ. et Helv. 8: 43. 1846.

Scirpus maritimus var. *umbellatus* Reich. op. cit. 1846.

Scirpus maritimus var. *monostachyus* Sonder, Fl. Hamb. 27. 1851.

Reigera maritima Opiz, Sezman 83. 1852.

Scirpus megastachyus Steud. Syn. Pl. Cyp. 87. 1855.

Scirpus squarrosulus Steud. *op. cit.* 88. 1855.

Isolepis grandispica Steud. *op. cit.* 318. 1855.

Scirpus ehrenbergii Boeckl. Linnaea 36: 716. 1869-70.

Scirpus laciniatus Nees & Ehr. ex Boeck. *op. cit.* 1869-70.

Scirpus hyalinolepis Steud. ex Jardin, Bull. Soc. Linn. Normand. Ser. II. 9: 278. 1875.

Scirpus nobilis Ridl. Trans. Linn. Soc. ser. 2. 2: 159. 1884.

Scirpus koshewnikowii Litw. In the list of Wild Plants of the Tambov Gov. 142. 1888.

Bolboschoenus maritimus Palla, in Koch. Syn. III. 2532. 1904.

Bolboschoenus compactus Drob., Trav. Mus. Bot. Acad. Petersb. 11: 92. 1913.

Bolboschoenus macrostachys Grossh. Flora Caucasus 1: 145. 1928.

Scirpus ewersanii Fisch. ex Litw. Acta Hort. Petrop. 40: 271. 1929.

Culms up to 8 dm. tall, often 1 cm., in depauperate forms, slender, erect from smooth, horizontal rhizomes, the roots slightly spongy, only at the nodes; the secondary rootlets inconspicuous; culms thickened at the base, sheathed at least half their height, sharply trigonous, at most only very obscurely scabrous, near the summit; very leafy, the sheaths green, the orifice truncate, hyaline, the blades mostly 5 dm. long, seldom over 5 mm. wide, the margins and midrib scabrous at tips; bracts of the inflorescence 1-5, leaflike, unequal, the outer up to 2 cm. long, the others progressively shorter, margins and midrib scabrous; inflorescence of one to many spikelets 1-3.5 cm. long, 5 mm. broad, oval to ovate acute, sessile or umbellate; primary rays up to 4.5 cm. long, smooth, the scales ca. 7 mm. long, the midrib prolonged 2 mm. beyond the bifurcate apex, brown, minutely hairy; bristles 2, nearly equaling the achene, retrorsely barbed; stamens 3; style 2-fid, or rarely 3-fid, 6 mm. long, achenes 3.5 mm. long, 2 mm. broad, dark brown, shiny, punctulate, compressed-trigonous. August-September.

Type in the Linnaean Herbarium.

Range: throughout Europe, occasional in Asia; Atlantic coast of North America from Nova Scotia to New York.

EURASIA: sheets seen from Russia, Roumania, Denmark, Sweden, Finland, Germany, France, England, Spain, Switzerland; rare in Australia, Japan, China, Siberia where probably introduced.

CANADA: New Brunswick, Northumberland Co., Blake 5707; Charlotte Co., Whale Cove, Weatherby & Weatherby 5609.

PRINCE EDWARD ISLANDS: Queens Co., Fernald et al. 6980.

NOVA SCOTIA: Truro, Fassett 2194; Shelburne Co., Jordan Falls, Fernald & Long 23398; Colchester Co., Fernald & Wiegand 4249.

MAINE: Washington Co., Moose Island, Fernald 1413; Knox Co., South Thomaston, Bissell et al. 8943; York, Bicknell 1156.

NEW HAMPSHIRE: Sea Brook, Eaton 507; Portsmouth, Davis in 1894; Hampton Falls, Eaton in 1898.

MASSACHUSETTS: Essex Co., Herb. Oakes; Scituate, Rich in 1901; Egypt, Williams in 1901.

RHODE ISLAND: Olney.

CONNECTICUT: Milford, Eames 39.

NEW YORK: Long Beach, Bicknell.

NEW JERSEY: Camden, Martindale.

The widely accepted interpretation of typical *Scirpus maritimus* is adopted here because it appears to agree with a photograph of the material in the Linnaean Herbarium. Two striking variations (among a host of lesser ones) occur throughout the species population. Because these are wholly without geographical identity and may be interconnected at many localities with the mean of the species and with each other, they are given only formal rank. The variation with a single sessile spikelet on a plant of reduced stature may be called *Scirpus maritimus* forma *monostachyus* (Sonder.). The other, of large size throughout and with a broadly cylindric-acute, usually rayed spikelets may be called *S. maritimus* forma *macrostachyus* (Lamb.).

4. *SCIRPUS maritimus* L. var. *fernaldi* (Bicknell) Beetle comb. nov.

Scirpus fernaldi Bicknell, Torrey 1: 96. 1901.

Scirpus campestris var. *fernaldi* Bartlett, Rhodora 8: 163. 1906.

Like the species but spikelets ovate, 1-2 cm. long, 1-1.5 cm. broad, sessile or 1-3 on smooth rays 3-5 cm. long; the achenes sharply trigonous.

Range: northeastern coast of North America from New Brunswick and Nova Scotia south to Maine and Massachusetts.

Type locality, Mt. Desert, Maine, August 20, 1898, Bicknell (N.Y.).

CANADA: New Brunswick, Gloucester Co., Miscous Is., Blake 5584; Nova Scotia, Cape Breton Is., Baddeck, Macoun 20,771; Colchester Co., Fassett 2193; Prince Edward Is., Summerside, Fernald et al. 6985, Mt. Stewart, Fernald et al. 6984; Quebec, Magdalen Island, Grindstone Is., Fernald 6986 & 6983.

MAINE: Washington Co., Whiting, Knowlton in 1916; Bristol, Chamberlin 695.

MASSACHUSETTS: Banks of Mystic River, Medford, W. Boott in 1859.

The trigonous achene and 3-fid style are especially significant in indicating that this entity is closely related to the European *S. maritimus* rather than to the American *S. paludosus*.

5. *SCIRPUS TUBEROSUS* Desf.

Scirpus corymbosus Forskal. Fl. Aeg.-Arab. 14. 1775; not L., 1756.

Scirpus tuberosus Desf. Fl. Atl. 1: 50. 1798-1800.

Scirpus aegyptiacus Poir. Encyc. Method. 6: 770. 1804.

Scirpus maritimus var. *tuberosus* R. & S. Syst. Veg. 2: 138. 1817.

Scirpus tridentatus Roxb. Fl. Ind. ed. Carey & Wall. 1: 228. 1820.

Scirpus cephalotes Heyne ex Roth. Nov. Pl. Sp. 30. 1821.

Culms up to 5 dm. tall, slender, erect from swollen nodes on slender black rhizomes; roots spongy, the secondary rootlets inconspicuous; culms sheathed to at least one-half their length, sharply trigonous, very obscurely scabrous at summit; very leafy, the sheaths green, the orifice conspicuously raised, hyaline, the blades mostly less than 5 mm. broad, margins and midrib scabrous at the tip; bracts of the inflorescence unequal the outer to 1 dm. long, the margins scabrous; inflorescence compound umbellate, of many spikelets, 1-2 cm. long, smooth, scales 7 mm. long, pubescent, light to dark brown, the apex notched, the midrib mucronate; bristles 6, fragile, unequal, shorter than the achene, retrorsely barbed; stamens 3, anthers 3 mm. long; style 3-fid, or rarely in the same spikelets 2-fid; achenes 2.5 mm. long, 2 mm. broad, trigonous, dark brown, slightly apiculate. June.

Type presumably somewhere in Europe. A collection from Algeria, Prov. de Oran, Coll. G.-L. Durando in 1852, specimen in the Gautier Herbarium of H. Knoche, San Jose, California, is here pointed out to be representative, as clearly as that is possible for one specimen.

Range: from Spain and Algeria along the coast of the Mediterranean Sea to the Caucasus; India.

Distribution: Eurasian specimens seen from France, Algeria, Syria, Central Asia (Trtysch Valley), Caucasus, and India (Punjab).

NEW YORK: Long Island, Queens, *Ferguson* 2396.

ALABAMA: *C. Mohr* in 1868.

The North American localities almost certainly represent random introductions.

Early in the study of this section of *Scirpus* it became evident that two specific entities were included in *S. maritimus* as it has been interpreted by European authors. True *S. maritimus* is most abundant on the northern coasts of France and Germany. A second species occurs around the Mediterranean Sea but never spreads far into northern Europe. The name *S. tuberosus* has been chosen for the latter for two reasons: (1) it is the first name which fits the plant applied to it in a region where it grows to the exclusion of *S. maritimus*, and (2) although the species is based principally upon a fallacious conception of the root system, the original description specifically mentions the shape of the spikelets as being different from the spikelets of *S. maritimus*.

6. *SCIRPUS ROBUSTUS* Pursh.

Scirpus maritimus var. *macrostachyus* Michx. Fl. Bor. Amer. 1: 32. 1803.

Scirpus macrostachyus Muhl. ex Spreng. Syst. Veg. 1: 211, Gram. 45. 1817, not Lam., 1791.

Scirpus robustus Pursh. Fl. Amer. Sept. 1: 56. 1814.

Scirpus maritimus var. *cylindricus* Torr. N. Y. Acad. Sci. 3: 323-325. 1836.

Scirpus decumans Willd. ex Kunth, Enum. Pl. 2: 168. 1837.

Scirpus strobiliferus Steud. Syn. Pl. Glum. Pars. 2, 317. 1855.

Scirpus maritimus var. *robustus* Kükenthal, ex Fedde, Repert. Spec. Nov. 23: 200. 1926.

Culms about 1 m. tall, stout, erect from swollen nodes on a smooth, black, horizontal rhizome; roots fibrous only at the nodes, the secondary rootlets numerous; culms trigonous, smooth, leafy nearly to the summit; leaf sheaths green, the orifice hyaline-margined and raised, the blades up to 6 dm. long, commonly 1 cm. broad, smooth below but frequently scabrous on the margins and midrib at the summit; bracts of the inflorescence 2-4, unequal, the outer up to 3 dm. long, the others progressively shorter; the margins and midrib scabrous, the spikelets 1-3 cm. long, 1 cm. broad, 3 to many, sessile or umbellate, single on short rays, ovate cylindric; primary rays up to 3 cm. long; smooth, scales 6 mm. long, 4 mm. broad, brown, minutely hairy, the strongly recurved midrib prolonged 2 mm. beyond the apex which sometimes appears bifurcate through splitting; bristles variable; style 3-fid; achene 3 mm. long, 2 mm. broad, lenticular or ovate, apiculate, dark brown, shiny. June-October.

Type not located; Pursh listed no specimens or localities in his original description. A collection from Florida, Duval County, Jacksonville, June 6, 1896, *A. H. Curtis* (U.C.) is here pointed out as representative of the species. This specimen has been chosen because (1) it is complete; (2) it is from a part of the range of *Scirpus robustus* not included in the ranges of other species in the section; (3) the collection is widely distributed (R.M., N.Y., Mo., G., F.M., U.S.).

Range: Atlantic coast of North America from Nova Scotia to Mexico, Bahamas, Brazil, Paraguay, Argentina; California.

CANADA: Nova Scotia, Victoria Co., Baddeck Bay, *Fernald & Long* 20, 215; New Brunswick, Gloucester Co., Bathurst, *S. F. Blake* 5457.

MAINE: Hancock Co., Franklin, *Friesner* 4649.

NEW HAMPSHIRE: Rockingham Co., Sea Brook, *Eaton* 507.

MASSACHUSETTS: Barnstable Co., Harwich, *Fernald & Long* 16378, Orleans, *Murdock* 705; Nantucket Co., *Pennell* 11,136; Essex Co., Newbury, 1898, *Williams*; Middlesex Co., Cambridge, 1912, *Kennedy*.

RHODE ISLAND: *Short*; 1891, *Congdon*; Newport Co., Block Island, *Fernald & Long* 8931.

CONNECTICUT: New London Co., Norwich, 1884, *Setchell*; Lyme, 1929, *Jansson*; New Haven Co., Milford, 1895 & 1898, *Eames*, *Blewitt* 3455.

7. *SCIRPUS robustus* Pursh var. *novae-angliae* (Britt.) Beetle comb. nov.

Scirpus novae-angliae Britt. in Britt. & Brown, Ill. Fl. 3: 509. 1898.

Scirpus campestris var. *novae-angliae* Fern. Rhodora 8: 163. 1906.

Like the species but the inflorescence more ample, the spikelets 6 mm. broad, up to 4 cm. long, cylindric-acute, many, sessile or on smooth rays, the primary up to 8 cm., the secondary up to 4 cm.; achene trigonous, dull brown.

Range: rare in coastal estuaries from Maine to Virginia.

Type locality, Connecticut, Fairfield, a fresh water marsh bordering creek, tide-water setting back to this point, July 19, 1896, *E. H. Eames* (N.Y.).

MAINE: Sagadahoc Co., Woolwich, *Fernald & Long 12,847*; Falmouth, *Fellows 5925*.

MASSACHUSETTS: Barnstable Co., Dennis, *Fernald & Long 18,061*, Barnstable, *Fernald & Long 18,062*.

RHODE ISLAND: Block Island, *Fernald & Long 8934*.

CONNECTICUT: Fairfield Co., Fairfield, 1896, *Eames*; Stratford, 1897, *Eames*; Lyme, *Harger 6601*.

NEW YORK: Westchester Co., between Glenwood & Hastings, *Bicknell 1174*; Long Island, Wading River, 1877, *Miller*.

NEW JERSEY: Salem Co., s.w. of Harrisonville, *Long 45,263*.

DELAWARE: Wilmington, 1866, *Commons*, Kent Co., Milford, 1908, *Long & Van Pelt*.

MARYLAND: Caroline Co., *Tatnall 2966*.

VIRGINIA: James City Co., Black River, *Fernald & Long 10,972*; Surry Co., e. of Scotland, *Fernald & Long 8593*.

The broad leaves, numerous secondary roots, coastal distribution, 3-fid style, and achenes all indicate the close relationship of this entity to *Scirpus robustus* rather than to *S. paludosus*.

8. *SCIRPUS FLUVIATILIS* (Torr.) Gray.

Scirpus maritimus var. *fluvialis* Torr. Ann. Lyc. N. Y. 3: 325. 1836.

Scirpus fluvialis Gray. Man. ed. 1: 527. 1848.

Culms 1-1.5 m. tall, stout, erect from swollen nodes on the horizontal rhizome; roots not spongy, the secondary rootlets numerous; culms trigonous, sheathed to one-half their height, smooth; leaf sheaths green, becoming dark brown, the orifice truncate, chartaceous; blades up to 6 dm. long; commonly 1 cm. wide, scabrous on the margins but the midrib smooth; bracts of the inflorescence 3 to 5, leaf-like, unequal, the outer up to 2.5 dm. long, the others progressively shorter, the margins and midrib scabrous; inflorescence umbellate, the spikelets 1-2.5 cm. long, to 1 cm. broad, ovate-acute, smooth; scales ca. 8 mm. long, the midrib prolonged 2 mm. from the tapered apex, brown, minutely hairy; bristles 6, variable, often equaling the achene, retrorsely barbed; stamens 3; style 3-fid, 1.5 cm. long; achene 4 mm. long, 2.25 mm. broad, trigonous, dull, gray-brown, punctulate, prominently apiculate, June-July.

Type locality "common in the western parts of N. Y., Gray" (N.Y.).

Range, throughout temperate North America; eastern Asia south to New Zealand, and New South Wales.

CANADA: New Brunswick, Sunbury Co., Burton, *Fassett* 2198; Kings Co., Westfield, *Fernald* 1412, *Fassett* 2200; Quebec, La Prairie Co., St. Lawrence River, *Svenson & Fassett* 1009; Montreal, *Victorin & Germain* 49,307; Ontario, Ottawa, *J. Specimens have also been seen from New South Wales, New Zealand, Japan, China and Siberia. These specimens agree essentially with the North American material in the achene but differ in the bifurcate apex of the scale.

SUMMARY

For the Section *Bolboschoenus* Palla of the Cyperaceous genus *Scirpus* six species and two varieties are recognized. A description, the complete synonymy and known geographic range are given for each species. *Scirpus strobilinus* Roxb. (1820) is upheld as an earlier name for the usually accepted *S. affinis* Roth (1821). *Scirpus tuberosus* Desf. which is usually included with *S. maritimus*, is recognized as distinct. Evidence for the newly suggested relationships implied by *Scirpus maritimus* var. *fernaldi* and *S. robustus* var. *novae-angliae* is given.

WATER LOSS FROM EXCISED LEAVES ¹

John Shafer, Jr.

IN STUDIES of physiological differences between various inbred and hybrid strains of corn (*Zea Mays*, L.), it is desirable to know if there are differences between the strains with respect to the water loss from the leaves, especially when transpiration is independent of possible differences in supply from the roots. This has application in studies of photosynthesis under conditions of high light intensity and rapid water loss, for consequent stomatal closure may interfere with assimilation. To determine if such differences exist, rates of water loss from excised leaves were determined by successive weighings.

The technic employed was to grow two inbreds and their hybrid side by side in pots in the greenhouse. No attempt was made to control environmental conditions. Immediately prior to an experiment, one healthy looking seedling plant of each strain was selected, and the potted plants were brought to the laboratory. The second, third or fourth leaves developed were used. Leaves were chosen which were fully developed but not old. Generally, the next higher leaf was almost fully expanded when the selected leaf was used. Usually only one leaf was used from each plant, but occasionally tests were made with a second leaf taken about one week after the first had been used. For any one experiment the leaves were all of the same position on the stem, *e.g.*, third from the base. The leaves were cut off in the laboratory, one at a time, and weighed. Subsequently, the leaves were weighed in turn again and again. The humidity of the laboratory was neither measured nor controlled; the light in the laboratory was diffuse. Since a weighing took about two minutes, each leaf was weighed every six or seven minutes. Between weighings the leaves were placed on galvanized iron wire mesh supported several inches above the desk top. The first weighing of each leaf was usually two minutes after cutting, and all leaves had been cut and

weighed once within ten or fifteen minutes after the plants had been removed from the greenhouse. After a few weighings, one weighing was omitted while leaf areas were determined with a planimeter. The leaves were weighed repeatedly for about 11½ hours, after which they were dried in a vacuum oven at 85°C. for several days and their dry weights determined. From the data were calculated total water loss per square inch, fresh weight per square inch, dry weight per square inch, percentage of dry matter in the fresh leaf, percentage of water in the fresh leaf, and percentage of water in the leaf at the start of "cuticular transpiration." Cuticular transpiration is the term used, in agreement with Stålfelt's terminology (1932, 1935), for the low and apparently constant transpiration rate attained eventually by the excised leaves.

The various strains differ from each other with respect to some of the statistics calculated. Since the differences seem independent of the inbred or hybrid nature of the plants, only a summary table of the results is presented here (table 1).

Each individual figure in table 1 is the average of ten or more separate values. All of the figures concerning any one set of strains (a set consisting of two inbreds and a hybrid) are averages of the same number of individual values. However, the different sets of strains were not employed the same number of times. Moreover, the different sets were grown and weighed at different times of the year. Consequently, caution must be exercised in comparing the data of any one set with those of the others.

Figure 1 is a graph of data from a typical experiment. Since most of the experiments were begun just afternoon on bright days, it is probable, in conformity with the work of Stålfelt (1932) and Pfeiderer (1933), that the initial rapid decrease in the rate of transpiration is due to a rapid closure of stomates as the water content of the leaf decreases. If this is

TABLE 1. Data concerning water and dry matter relationships of corn leaves.^a

Pedigree of plants	Total H ₂ O loss per sq. in.	Fresh wt. per sq. in.	Dry wt. per sq. in.	% H ₂ O fresh	% H ₂ O at start of cuticular transpiration	
	mg.	mg.	mg.			
#1 inbred	19.0	99.0	10.5	89.2	86.2	Vigorous hybrid
#2 inbred	7.4	87.9	9.5	89.0	88.6	
1×2 hybrid	10.5	91.5	9.9	88.8	87.8	
193 inbred	15.0	123.4	11.4	90.8	89.7	Vigorous hybrid
194 inbred	9.5	102.7	9.6	90.7	90.0	
193×194 hybrid	10.2	106.3	9.7	90.9	90.0	
190 inbred	16.1	83.8	11.3	86.3	83.3	Weak hybrid
191 inbred	10.4	83.4	10.2	87.6	85.5	
190×191 hybrid	9.7	82.1	10.3	87.3	85.9	

^a σ cannot be calculated because the duration of experiment and room humidities involved in individual experiments were somewhat different. The averages presented give only the relative relationships of the two inbreds and their hybrid.

true, it is probable that the apparently constant rate of transpiration attained after an hour's time represents the rate after the stomates have closed. It is this rate which is called in this paper "cuticular transpiration." The curve for #1 inbred in figure 1 resembles somewhat curve B in figure 1 (inset).

Two exceptional types of water loss were occasionally found. An example of each is shown in figure 1 (inset). Curve A is tentatively explained by assuming that the stomates were essentially closed at the beginning of the experiment and remained closed. Curve B is explained by assuming that the stomates

Many of the transpiration curves of the type in figure 1 have been plotted in this semi-log fashion. Since there seems to be no theoretical reason for supposing that lines fitted by the method of least squares, or by any of the other common technical procedures, should be more appropriate than lines sketched by sight, we have used the latter method of drawing in the lines. In nearly every case the fit of such lines seems satisfactorily close. To get more points, one experiment was done in which one leaf was weighed every two minutes. The results are shown in figure 2, curve D.

Fig. 1. Graph of data concerning water loss from excised corn leaves. Explanation in text.

were partly closed, that as the epidermal cells began to wilt they relaxed pressure on the guard cells and the stomates opened, later closing again as the guard cells lost turgor (cf. Stålfelt, 1929, 1932).

If the data shown in figure 1 are plotted semi-logarithmically, plotting the logarithm of "stomatal transpiration" ($r-d$) against time, a straight or nearly straight line is obtained. (See fig. 2.) Such a curve is represented by the equation²

$$\log (r-d) = bt + c$$

where t is the time elapsed after the cutting off of the leaf, r is the rate of total transpiration, determined from the difference between two successive weighings, d is the rate of cuticular transpiration, c is the estimated logarithm of stomatal transpiration at $t=0$, and b is the slope of the line. This logarithmic function becomes unsuitable when $(r-d)$ becomes less than one.

² We are indebted to Dr. J. H. Curtiss of the Mathematics Department of Cornell University for help with the mathematics employed in this paper.

The slopes of the curves for the various inbreds and hybrids, insofar as they were graphed, were nearly the same. (The different slopes in fig. 2 are not characteristic of the particular pedigrees.) This means that the decrease in the logarithm of stomatal transpiration was essentially independent of the strain of corn studied; this implies in turn that the speed with which the stomates close is independent of the strain of corn used. It seems unlikely that the stomates of six inbreds and three hybrids should all close at the same relative rates unless the same mechanism be operative in all cases. In the present case the closure of stomates is probably due to the rapid wilting of the entire leaf. It would seem that water loss by evaporation is so rapid that the usual osmotic and imbibitional influences of the guard cells are not given time to act. If this is true, such an experiment of weighing excised leaves can never measure differences in closure of stomates under such adverse conditions as are commonly met with, unless the humidity about the leaves is kept quite high. This was not done in the present experiments.

The water losses from a few excised bean leaves (*Phaseolus vulgaris* L., var. Red Kidney) gave linear graphs when plotted in the above-described semi-log fashion. Furthermore, the data given by Stålfelt (1932) for an excised birch leaf and by Paltridge and Mair (1936) for whole plants of a number of different Australian grasses seem also to fit a semi-logarithmic straight line of the type mentioned. The same is true for data given by Pfeiderer (1933) concerning water loss from excised shoots of a number of plants, including *Stachys germanica*, *Picea excelsa*, *Buxus sempervirens*, and *Sambucus nigra*.

Pfeiderer's (1933) and Stålfelt's data (1932) for width of stomates also fall into a straight line with semi-log plotting. Their data for stomate width and "stomatal transpiration," plotted against each other on log-log graph paper, fall in a straight line.

These similarities of stomatal closure and "stomatal transpiration" strengthen the assumption that the initial rapid decrease in rate of water loss is due to closure of stomates. The diverse sorts of plants that show a semi-logarithmic relationship between stomatal transpiration and time, when all external sources of water supply are removed, make it seem probable that such a relationship is very general. However, it will presumably appear only when parts of plants are excised, or when entire plants are pulled up.

SUMMARY

Excised leaves of various inbred and hybrid corn seedlings were weighed repeatedly until the rate of water loss became constant. The various statistics calculated from the data so obtained were independent of the pedigree. Thus, no real differences between strains with regard to water loss were found.

The data obtained seem to fall in a straight line curve when the logarithm of stomatal transpiration is plotted against time. It is concluded that such a semi-log relationship between water loss and time is general for excised leaves and for living plants unable to absorb water.

SOME EFFECTS OF PHOTOPERIOD ON LEAF GROWTH¹

Irene H. Stuckey

It is generally recognized that, irrespective of the flowering response of plants grown with different photoperiods, vegetative growth is most prolific under exposures of sixteen to eighteen hours (Austin, 1935; Weaver and Himmel, 1929; Doroshenko, 1927). If the critical period for a long-day plant is reached and flowering occurs, the weight may be less than that of a short-day vegetative plant, but usually the plants grown with long photoperiods are consistently larger.

In their classical papers on photoperiodism, Garner and Allard (1923) recognized the influence of day-length on the vegetative development of plants as well as on flowering, but, with few exceptions, most of the investigations following these have been

the inhibition of stem elongation as the simplest evidence of photoperiodism.

The results reported here developed from the observation that several species of grasses growing with eight- and sixteen-hour photoperiods showed striking differences in habit of growth. The plants exposed to an eight-hour photoperiod tended to be prostrate in their growth habit. The plants which received a sixteen-hour photoperiod had relatively few tillers, and the habit of growth was strongly ascending. Both the sheaths and the blades of the leaves were much longer in proportion to the width than those of plants growing with the shorter photoperiod. An early stage during the growth of orchard grass is shown in figure 1.

There was some speculation as to whether these differences in habit had any recognizable anatomical basis, and if so, whether it could be measured, and an investigation along these lines was begun. The points to be considered were the relation between leaf size and cell number and differences among the cells. Were the leaves longer because they contained more cells or larger cells? Were the leaves of the plants growing under the long day more erect because they contained more mechanical tissue, or was the mechanical tissue more rigid than that in the plants exposed to the short day?

EXPERIMENTAL.—Materials and methods.—Of the several species of grasses in which this phenomenon was noticed, orchard grass (*Dactylis glomerata* L.) seemed best adapted for an anatomical study. The leaves are long and relatively wide. It grows readily under greenhouse conditions, and the change from the vegetative state to flowering can be detected by the elongation of the first internode even before flower primordia can be found with dissection.

Commercial seed of orchard grass was planted in fertile soil in greenhouse beds and, after several weeks, the plants were thinned to the desired spacing. The first series of plants was grown from October through December and the second from January through June. Four beds were used. Two beds received eight hours of daylight and were shaded with black sateen curtains during the remainder of the day. The other two beds were given supplementary light which increased the photoperiod to sixteen hours. On days when the intensity of daylight was very low, all beds received supplementary mazda light during the daylight period.

Leaf samples were collected approximately every two weeks, the youngest fully expanded leaf from several plants being taken each time. The leaves were considered fully developed when the base of the blade had emerged from the sheath of the next older leaf. The leaves were boiled in 70 per cent alcohol until the chlorophyll was extracted and then stored in fresh 70 per cent alcohol until needed.

To study the lengths of the cells in the leaves, macerations from the midribs were made according

Fig. 1. Orchard grass growing with two different photoperiods. The plant on the left was exposed to a sixteen-hour day, the plant on the right to an eight-hour day, and the one in the center to natural day length. The photograph was made November 20, 1939, when the plants were four weeks old.

concerned with the induction or inhibition of flower primordia. Murneek (1940) has distinguished between photoperiodic effects on the vegetative growth and flowering of *Rudbeckia*. Went (1941) reported the effects of light on stem and leaf growth; he cites

Contribution No. 601 from the Rhode Island Experiment Station.

to the method of Jeffery as described by Johansen (1940). The midribs were dissected from the laminae and macerated at 58°C. in a mixture of dilute chromic and nitric acids, the time and strength of the solution varying with the material. The time required for successful maceration of midribs from plants exposed to the sixteen-hour day was usually twice as long as for those collected at the same time from plants growing with the eight-hour day. When the maceration had progressed until the cells would separate readily and yet not disintegrate, the material was washed thoroughly with water. Small portions were stained with safranin, then destained with 95 per cent alcohol, cleared in diaphane solvent and finally mounted in diaphane. This is a relatively simple method for obtaining large numbers of isolated cells which can be measured easily with a calibrated ocular micrometer.

Since these macerations gave only longitudinal views of the midribs, cross sections were made from some of the same material. Short lengths of the midribs were embedded in paraffin after being run through the n-butyl alcohol series. The sections were stained with Heidenhain's hematoxylin and safranin.

Epidermal cells were counted directly on known areas of tissue, and estimates of the number of cells in the leaf were derived from these counts.

At intervals, the length and width of the longest leaf from fifty plants were determined, and the numbers of tillers on the plants were counted. The color of the plants grown with the eight-hour photoperiod seemed to be a more intense green than those grown with the long day, but no attempts were made to measure any differences.

Results.—Examination of the macerations showed that the mesophyll cells were the same size in all the preparations, and no measurements of these cells were taken. Most of the annular vessel elements were torn, but the reticulate elements were intact and easily measured. Since the end wall perforations were distinctive, broken segments of vessel elements could be recognized and discarded. The lengths of the vessel elements from both series are shown in table 1. There were greater individual variations in the lengths of the fibers, but a larger number was measured to compensate for this as shown in table 2. The differences in length of the fibers were even more significant than those of the vessel elements. The dif-

ferences both in vessel elements and fibers were greatest when the plants were growing most rapidly, tending to level off toward the end of the growing period.

A parallel experiment was performed with Colonial bent (*Agrostis tenuis* Sibth.). The results were essentially the same as those shown on tables 1 and 2 and are not included here.

The estimate of the numbers of epidermal cells in the leaf, based on counts from known areas of the leaves (table 3), indicate that here also the length of the cells in the leaf was increased rather than the number of cells. The width of the leaves increased very little in proportion to the length (table 4). It was not determined whether a greater number of mesophyll cells was present in the leaves from the plants under the sixteen-hour photoperiod, or whether the intercellular spaces were larger.

Fibers seemed to be more numerous in the preparations made from the long-day plants. Cross sections of the midribs showed that, while there was a small increase in numbers of the fibers as is shown in the second row of fibers on one side of the bundle (fig. 2), the apparent increase is due to the greater

length of fibers. Many of the fibers were long and twisted and could not be measured easily. The most noticeable difference in the cross sections of the midribs was the striking wall thickness of the fibers grown with the long photoperiod. The phloem in the leaf from the long-day plant (fig. 2) appeared less mature than that from the short-day plant; yet the fiber walls were much thicker. This wall thickening probably accounts for much of the increase in rigidity of the leaves of the long-day plants.

Murneek (1940) has observed that in *Rudbeckia*, the position of the leaves changes from horizontal to vertical after induction of flower primordia has taken place, but none of the orchard grass plants used here ever changed to the flowering condition. At the end of the experiment neither elongated internodes nor primordia were found on any of the plants.

DISCUSSION.—Tincker (1925), using clonal stock, found that orchard grass responded as a long-day plant. He presented evidence that the treatment of plants during one season influenced the flowering response the following year. Sprague (1941) more recently observed that none of the clonal material he was using headed under normal winter days nine to

ten hours long. Several clones headed and flowered under a twelve-hour day, but the type of growth was very decumbent, and heading was three or four weeks later than that obtained under a sixteen-hour day. While not all of the clones headed with the sixteen-hour day, a considerably larger number produced erect normal heads. Sprague believes that the treatment of an orchard grass plant for six to ten

of photoperiod on cell length was not further complicated by the effects of photoperiod in inducing flower primordia. All the plants used here were vegetative.

The effects of light on the growth of leaves have been studied by several workers. Gregory (1921) considered that the area of the leaf surface is closely related to the intensity of incident radiation. Went

Fig. 2. The section on the left was taken from the midrib of a leaf grown with a sixteen-hour day, that on the right from one exposed to an eight-hour day. The plants were collected April 18, 1940.

weeks prior to a long photoperiod conditions the response of the plant to the photoperiod.

The writer has found, when using seedlings in experiments similar to those just described, that eventually a small percentage of the plants flowered under an eight-hour day if the experiments were continued for eight months, but the critical photoperiod seemed to be no more than twelve hours. Formation of flower primordia was never induced with a sixteen-hour photoperiod during the course of these experiments. It was not determined whether the contradictory results obtained with the seedlings by the writer were due to the strain of orchard grass used, or whether the response of the clones used by other workers was influenced by the environmental conditions to which they were exposed prior to the photoperiod experiments. Under these conditions the assumption can be made that the study of the influence

(1941) found that within the range of $1/10,000$ ergs/cm.² each day the leaf length is proportional to the log of the amount of energy supplied. With more light the effect falls off, as might be expected. Undoubtedly at lower intensities the incident radiation is the limiting factor in leaf growth, but for most plants photoperiods from sixteen to eighteen hours give maximum vegetative growth, longer periods resulting in injury. The unequal growth of the orchard grass leaves cannot be explained as being caused by differences in the total radiation. The evidence strongly suggests that the differences in leaf size are responses to the differences in photoperiods. Tincker (1928) reported that in early spring the leaves of orchard grass had short sheaths, and, as the days became longer in May and June, leaves with longer sheaths were produced.

Investigations of the influence of photoperiod on the anatomy of leaves have been conducted by Deats (1925), Pfeiffer (1926) and Tincker (1928), but they were incidental to a study of the anatomy of the stems. These workers found differences in leaf thickness which were due to elongation of the palisade cells, but environmental factors other than photoperiod seemed to play some part, since results with the same species were not always consistent. No references were found including studies of midribs of leaves of any species. Redington (1929) measured the length of leaves of *Pelargonium*, *Polygonum* and *Chrysanthemum* growing with different photoperiods, entirely with artificial light. In every case, the laminae were largest with the sixteen-hour photoperiod. In no instances were any cell measurements made.

Most of the anatomical studies of the effect of photoperiod have dealt with stems almost exclusively, and insofar as only primary tissues are involved, the results may be considered applicable to these same tissues in leaves. Redington (1929) found that the linear dimensions of the endodermal cells in the stems of flax, hemp, hop, salvia, hibiscus, and cotton varied inversely with the light period. His photographs show that the use of artificial light alone caused marked etiolation, especially in the plants growing with the eight-hour photoperiod.

Doroshenko (1927) found that within limits the cell size in stems of flax became smaller as the day length was decreased, then below a certain level began to increase again. In some strains of wheat, the leaves were more numerous and longer under a nine-hour day as compared with a twelve-hour day or normal summer day length. However, his results can be attributed to a difference between vegetative and reproductive growth rather than the effect of photoperiod on vegetative growth.

A striking difference noticed in the midribs of the orchard grass leaves, which is comparable to results reported by others in stems, was the marked thickening of the walls of the sclerenchyma of the bundle sheaths. Such wall thickening was noted in the stems of several species of perennial plants by Redington and Priestley (1925). The thinness of the walls of fibers grown with an eight-hour light period was especially striking. Deats (1925) observed that in pepper and tomato plants the walls of the "bast" were thicker, and that in pepper the walls of the xylem also were thicker, in the plants growing with the long photoperiod. In these plants, the epidermal cells of the stems were longest with the long photoperiod.

At present no theories are presented which will explain the differences found in cell length. More carefully controlled conditions are necessary to determine whether the difference found was caused primarily by photoperiod or by some other factor.

SUMMARY

Orchard grass seedlings grown in eight- and sixteen-hour photoperiods were very different in size and habit of the plants. Plants grown under the long photoperiod were characterized by longer leaves and more erect growth habit. These differences were correlated with the following differences in their anatomy:

1. The lengths of the vessel elements, of the fibers and of the epidermal cells, varied directly with total organ size, indicating that leaf length differences were due to cell size and not cell number, at least with respect to these cell types.

2. The size of the mesophyll cells remained the same; hence size differences in this tissue may be due either to differences in cell number or in the size of the intercellular spaces.

3. The walls of the fibers were noticeably thicker

in long-day plants which is probably correlated with their more upright habit, but no such difference was observed in the walls of vessel elements.

FACTORS CONTROLLING SPORANGIAL TYPE IN THRAUSTOTHECA PRIMOACHLYA AND DICTYUCHUS ACHLYOIDES. I¹

S. B. Salvin

THE GENERA of the Saprolegniaceae are distinguished from one another by their methods of asexual reproduction, i.e., by the characteristics of the sporangium, the type of spore discharge, and the extent of the swarmer cycle. Although originally but one method of sporangium dehiscence was known for each genus, three species are now recognized in which two methods are present, each of which is representative of a different genus. In *Thraustotheca primoachlya* (Coker and Couch, 1924), the spores of the initially formed sporangia, after emergence through an apical papilla, become arranged in a rather irregular hollow sphere at the sporangial apex as in the genus *Achlya*, whereas those of the later sporangia are liberated through an irregular rupture of the outer sporangium wall as in the genus *Thraustotheca*. In *Dictyuchus achlyoides* (Coker, 1927), the sporangia are at first of the *Achlya* type, but are replaced subsequently by those characteristic of the genus *Dictyuchus*, in that they have a "cell-net" structure with the zoospores emerging separately from individual compartments. In *Brevilegnia bispora* (Couch, 1927), which may better be called

Thraustotheca bispora (Salvin, 1942), the mycelium first gives rise to sporangia characteristic of the genus *Achlya*, but later to those characteristic of the subgenus *Brevilegnia*, in which the sporangiospores are dispersed by an irregular rupture of a very thin sporangial wall. These two latter forms will for convenience be termed "achlyoid" and "brevilegnoid" respectively.

Although these transformations in the methods of sporangial dehiscence have been carefully described, little is known about the basic causes. The assumption has been that the change is purely of genetic origin, although no experimental work has been reported to establish this belief. However, if the environment does produce, partly or wholly, the change in the sporangia, not only may the true taxonomic position of the species then be clarified, but also new facts on the relationship of the genera of the Saprolegniaceae may be forthcoming. Accordingly, the writer conducted investigations on *Thraustotheca primoachlya* and *Dictyuchus achlyoides* in order to determine the exact basis for the appearance of two distinct types of sporangia on the same mycelium in each of these species.

MATERIALS.—Most of the experimental work was conducted on two species: (1) *T. primoachlya*, isolated from soil along the Charles River, Cambridge, Massachusetts, by J. R. Raper; and (2) *D. achlyoides*, isolated by Ralph Emerson from mud obtained

¹ Received for publication September 15, 1941.

Contribution from the Laboratories of Cryptogamic Botany and the Farlow Herbarium, Harvard University, no. 198.

The writer expresses his sincere appreciation to Professors W. H. Weston and K. V. Thimann for their advice and criticism during this study.

from a swamp in Kampala, Uganda, Africa. A few experiments were also done on other species.

EXPERIMENTS AND RESULTS.—*Normal life cycles.*—When *T. primoachlya* was grown on a hemp seed in 25 cc. of redistilled water at room temperature (22° to 23°C.), all the sporangia formed during the first three days were achlyoid. Subsequently, although many sporangia still liberated their spores as in *Achlya*, more and more began to dehiscence in the thraustothecoid manner until, from the fifth day on, all the sporangia were of the latter type.

When *D. achlyoides* was grown under the above conditions, both achlyoid and dictyuchoid sporangia were produced in large numbers during the first two days. Thereafter, the quantity of newly formed achlyoid sporangia rapidly dwindled, until by the end of the third day only the "cell-net" type was developed.

If transformations in the sporangia are due to changes in the environment, three possible influential factors must be considered: (1) a decrease in the oxygen tension; (2) the presence of a critical hydrogen ion concentration; or (3) the accumulation of an active staling substance.

Investigations on the influence of a decrease in oxygen tension.—Since the fungus mycelium is aerobic, it requires oxygen in amounts sufficient to permit the normal functioning of the metabolic processes. If this oxygen were to be consumed by the hyphal mass from the aqueous medium at a rate greater than that at which it is being replenished from the external air, a concentration might result which would disrupt the internal processes to such a degree that the morphology and behavior of the sporangia become altered. If, however, a continuous supply of oxygen is available, then no change in the sporangia should occur.

One hemp seed inoculated with *T. primoachlya* was suspended in a microaquarium in 25 cc. of water through which air was being bubbled, and another similarly inoculated was placed under the same conditions, except that the air was obtained by diffusion through the surface of the water. The mycelium in the vigorously aerated water formed achlyoid sporangia at first, just as in the control, and for about the same length of time, although comparatively few sporangia were formed at all. Evidently, therefore, a decrease in oxygen tension is not the factor responsible for the change in sporangial type.

Investigations on the influence of hydrogen ion concentration.—As the mycelium of *T. primoachlya* developed, the 25 cc. of aqueous medium gradually became more alkaline, the hydrogen ion concentration decreasing from pH 5.5 on the first day of growth to pH 7.3 on the fourteenth, with the change in sporangial type from achlyoid to thraustothecoid occurring at pH 6.3 to 6.7. These results suggest that the presence of a critical hydrogen ion concentration in the external medium may induce the formation of thraustothecoid sporangia exclusively.

This, however, was demonstrated to be untrue. When *T. primoachlya* and *D. achlyoides* were each

grown in 25 cc. of M/50 phosphate-buffer solutions of pH 3.5 to 8.6, achlyoid sporangia were the first to appear in all the cultures. If the alkalinity of the water did influence the nature of the sporangia, only thraustothecoid would have developed in the solutions with a pH above 6.5 and only achlyoid in those below about 6.5. Hence, the conclusion can be drawn that the change in the sporangia is not associated with a decrease in hydrogen ion concentration.

Investigations on the influence of staling material.—Since the products of mycelial metabolism are excreted into the surrounding medium, there is the possibility that the attainment of a threshold concentration of a staling substance may influence the behavior of the sporangia. In order to prevent the accumulation of any such active staling substance and, therefore, to inhibit the formation of thraustothecoid sporangia, a mycelium of *T. primoachlya* was grown on a hemp seed in 25 cc. of glass-distilled water which was constantly being renewed by a perfusion apparatus (Raper, 1939). Here again the sporangial cycle was typical, with great numbers of achlyoid sporangia appearing first and then being succeeded by thraustothecoid. When similar experiments were carried out with tap water, ordinary distilled, glass-distilled plus salts, and spring water, similar results were obtained.

However, when *T. primoachlya* grew on a hemp seed in 25 cc. of water in which another colony of the same organism had previously developed for two weeks, only thraustothecoid sporangia were formed. Some substance evidently had been excreted which inhibited the production of achlyoid sporangia.

That this active staling principle was not specific to the mycelium of *T. primoachlya* was shown when similar experiments were conducted with the staling substances from other species. After *Achlya flagellata* Coker, *Aphanomyces laevis* deBary, *D. achlyoides*, *Dictyuchus* sp., *Saprolegnia* sp., *Thraustotheca clavata* (deBary) Humphrey, *T. primoachlya*, and *T. unispalma* Coker and Braxton had each been grown on twenty hemp seeds in 25 cc. of water at 25°C. for ten days, the water from each species was drawn through a Chamberland filter and used again for the growth of *T. primoachlya* on a single hemp seed.

Four types of responses by the mycelium of *T. primoachlya* were discernible: (1) formation of many sporangia of both achlyoid and thraustothecoid types; (2) development of only thraustothecoid sporangia, with complete suppression of the achlyoid; (3) extensive mycelial growth, with a tendency toward suppression of all sporangia, but with thraustothecoid sporangia predominating among the few formed; and (4) inhibition of both sporangium formation and vegetative growth. The extent of the influence of the different species was related to the rate of their mycelial growth (fig. 1), since the species with extremely rapid growth (e.g., *Saprolegnia* sp.) inhibited the mycelial and sporangial development of *T. primoachlya*; those with intermediate rates (e.g., *T. clavata*) inhibited completely the development of

achlyoid sporangia, and partially that of thraustothecoid sporangia, but actually increased vegetative growth; and those with low rates (*e.g.*, *Aphanomyces laevis*) either inhibited slightly the development of achlyoid sporangia or had no influence whatsoever.

Many genera evidently produce a substance, or substances, which, if present in the proper amount, influence the type and number of sporangia of *T. primoachlya*. As the species with the highest growth rate has the greatest influence on the sporangia of *T. primoachlya*, this same species probably produces the most staling material.

When a colony of *T. primoachlya* is developing under normal conditions, this active principle is probably excreted continually into the water, in relatively small quantities of which a definite threshold is attained that results in the transformation in the type of sporangium. The time necessary for the appearance of the threshold concentration should, therefore, increase in proportion to the volume of water present.

To test this concept, single hemp seeds inoculated with *D. achlyoides* and *T. primoachlya* were placed in quantities of water from 1 cc. to 3,000 cc. and the time recorded when achlyoid sporangia ceased being developed. The results were clear-cut and in support

Fig. 1. Graph, showing the rate of mycelial growth of eight different species of the Saprolegniaceae. (AF, *Achlya flagellata*; AL, *Aphanomyces laevis*; BU, *Thraustotheca unispersma*; D, *Dictyuchus* sp.; DA, *Dictyuchus achlyoides*; S, *Saprolegnia* sp.; TC, *Thraustotheca clavata*; TP, *Thraustotheca primoachlya*.)

of the above view (fig. 2). In *T. primoachlya*, no achlyoid sporangia at all were apparent in either 1 cc. or 2 cc. of water. In 5 cc., some achlyoid sporangia were formed, but these were entirely replaced by thraustothecoid in 24 hours. In 10 cc. of water, achlyoid sporangia no longer were developed after about 70 hours; in 25 cc., after 105 hours; in 50 cc., after 144 hours; in 100 cc., after 270 hours; etc. Similar results were obtained for *D. achlyoides*,

although in this species achlyoid sporangia were always accompanied by dictyuchoid and were formed for comparatively briefer periods in the corresponding volumes of water.

To establish a broader basis for the concept that a threshold concentration of a staling material inhibits the development of achlyoid sporangia, a colony of *T. primoachlya* on a hemp seed was grown in

Fig. 2. Graph, illustrating the relation between (1) the volume of water in the culture, and (2) the time of cessation of formation of achlyoid sporangia.

1 cc. of water for 24 hours, during which time only thraustothecoid sporangia appeared. When the mycelium was transferred to 40 cc. of water and examined twelve hours later, many achlyoid sporangia were apparent. On removal to 1 cc. of water, the hyphal mass again formed only thraustothecoid sporangia.

These facts seem to justify the conclusion that the mycelium gradually excretes an active substance which inhibits the formation of achlyoid sporangia when a threshold concentration is reached. Although the active principle is apparently present in many species, its exact nature has not been determined as yet.

Relation of the staling substance to oxygen tension.—Preliminary experiments on the influence of aeration on the formation of sporangia in *T. primoachlya* showed that increased amounts of oxygen failed to inhibit the development of thraustothecoid sporangia. However, the hyphae of *T. primoachlya* on the surface of 50 cc. of water formed thraustothecoid sporangia at least twenty-four hours before those below the surface. Since these surface hyphae are exposed to a rather high oxygen tension, the rate of formation of the active staling material may conceivably be increased thereby, and as a result thraustothecoid sporangia would appear comparatively early.

That this hypothesis is true is indicated by the following experiment. Mycelia of *T. primoachlya* were grown on single hemp seeds in 200 cc. quantities of water (1) in a large Petri dish 19 cm. in diameter, (2) on the surface in a crystallizing dish 9 cm. in diameter, and (3) at a depth of 4 cm. in a similar crystallizing dish. In (1), achlyoid sporangia were replaced by thraustothecoid after 116 hours; in (2), after 142 hours; but in (3), achlyoid sporangia were still being formed 350 hours after the time of inoculation. These results do indicate that a high oxygen tension hastens the rate of formation of the active staling substance.

Fig. 3. Graph, showing the rate of production of ammonia by *Thraustotheca primoachlya*.

Investigations on the ammonium ion, or ammonia, as the active staling principle.—Since the water in which cultures of either *T. primoachlya* or *D. achlyoides* were developing gradually increased in alkalinity and contained much ammonia, as indicated by a positive reaction on the addition of Nessler's reagent, it seemed possible that ammonia, or the ammonium ion, initiated the change in sporangia. Accordingly, experiments were conducted to cast further light on this point.

In order to determine at what concentration of ammonia the change in sporangia occurred, the rate and extent of ammonia formation were measured. Fifty inoculations of *T. primoachlya* on single hemp seeds were made in dishes each with 25 cc. of water and grown at 25°C. for over 200 hours. Every few hours, 5 cc. were removed from successive dishes and the amount of ammonia determined by the addition of two to three drops of Nessler's reagent and the subsequent comparison with a standard solution of ammonium hydroxide in a colorimeter. The concentration of ammonia increased from about $5 \cdot 10^{-7}$ M. at 40 hours to over $5 \cdot 10^{-4}$ M. at 220 hours, with the change in sporangia appearing at about $5 \cdot 10^{-5}$ M. (fig. 3).

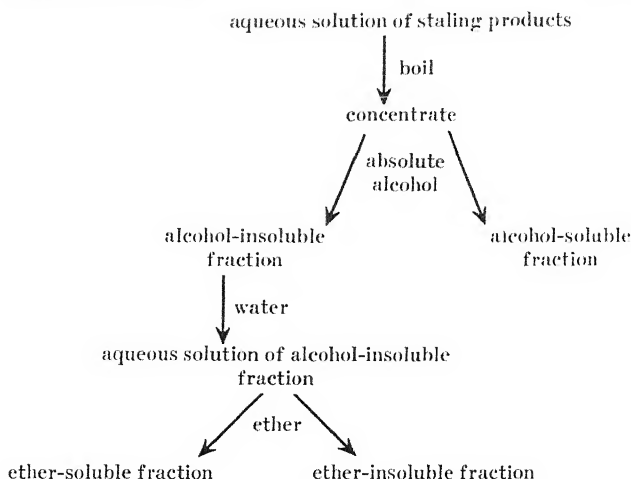

With the concentration established at which the change in sporangial type occurred, both *T. primoachlya* and *D. achlyoides* were grown in solutions of several ammonium compounds and examined for indications of the inhibition of achlyoid sporangia. To exclude the possibility that the anion influences the development of the sporangia, mycelia of the two species were also grown in solutions of compounds which had the same anions as the ammonium mole-

cules but different cations. The results are summarized in the accompanying table (table 1).

In the first place, it is clear that three of the four ammonium compounds did influence the formation of sporangia in *T. primoachlya*, and one of the four had such an effect in *D. achlyoides*, in contrast to the sodium and potassium compounds, which had no visible effects whatsoever. On the other hand, the significance of the rôle of ammonia in the transformation of sporangia is greatly lessened in view of (a) the lack of definite correlation between the concentration of the (NH_4) ion and the formation of a particular sporangial type and (b) the frequent appearance of abnormal vegetative growth. For example, in *T. primoachlya*, only in some of the solutions of ammonium sulfate did complete inhibition of achlyoid sporangia appear, although in several of the ammonium chloride and ammonium carbonate solutions the initially formed sporangia were both achlyoid and thraustothecoid. The inhibition of the development of achlyoid sporangia did not take place at the same concentration of ammonia, the variation being from 0.042 grams of ammonia per liter in the ammonium chloride solution to less than 0.003 grams per liter in the ammonium carbonate solution. These concentrations of ammonia do not agree closely with the one occurring when the transition in sporangial type appears in normal cultures, namely, 0.009 gram per liter. In addition, as the solutions with increased concentrations of ammonia were tested, the vegetative mycelium became abnormal, as characterized by stunted growth and gnarled hyphae, in several cases even before there was any noticeable effect on the sporangia.

These results indicate that ammonia, although produced by many species as a byproduct of normal metabolic processes, is not the principal substance that causes the change in the sporangia, although possibly it does function in some minor rôle.

Investigations on the properties of the staling material.—With the conclusion that the ammonia in the staling material was not in itself the active sub-

stance that induced the transition from achlyoid to either thraustothecoid or dictyuchoid sporangia, direct analysis of the staling products of *T. primoachlya* was attempted. Relatively large quantities of the substance were obtained in the following manner. After the organism had grown in a solution of 1 per cent gelatin, 0.5 per cent peptone, and 0.5 per cent dextrose for about a month, the mycelial mass was thoroughly washed in sterile water in order to remove all adherent nutrient and allowed to develop in glass-redistilled water for an additional three weeks. The resultant solution was then drawn through a Chamberland (porcelain) filter in order to eliminate spores, bits of hyphae, and particulate matter. Since no ingredient of the liquid boiled at less than 100°C . and since the staling principle was not destroyed by several hours of heating at 100°C ., the excess water was slowly evaporated through a Hempel fractionating column without apparent loss of, or change in the staling material. During this condensation, the solution gradually assumed a color first of golden yellow and then of grayish brown.

This concentrate from a liter of water in which the mycelium from 12,000 cc. of nutrient solution had been present for three weeks completely inhibited the development of achlyoid sporangia. The concentrate was still effective in dilutions up to 250 times. The staling material was also active after exposure to a temperature of 250°F . and a pressure of 15 pounds per square inch for 45 minutes, but not after treatment with either strong acid or alkali. In addition, it was very soluble in water, very slightly soluble in ethyl alcohol, and insoluble in ether.

The separation of some of the components of the staling material produced very interesting results. On the addition of 250 cc. of absolute ethyl alcohol to a 10 cc. concentrate of staling material, an extremely fine, grayish-white precipitate appeared, which was then separated from the otherwise clear, pale amber alcohol solution by centrifugation and dissolved in 10 cc. of water. Whereas, after the evaporation of the alcohol, the extract was tested di-

rectly, the aqueous solution of the precipitate, in contrast, was further subjected to fifteen successive extractions of 50 cc. volumes of ether. The resulting residue was dark brown in color, in contrast to the extract, which, after the boiling off of the ether, was colorless (cf. diagram 1).

a. *Alcohol-soluble fraction*.—When *T. primoachlya* was grown on a hemp seed in either 25 cc. or 50 cc. of an aqueous solution of the alcohol-soluble fraction, the vegetative growth, if present at all, was limited to 2 to 3 mm. in diameter and the production of sporangia was completely inhibited (fig. 4 A).

Fig. 4. Photograph, illustrating (A) inhibition of mycelial growth of *Thraustotheca primoachlya* by alcohol-soluble fraction, (B) normal mycelial growth, and (C) increase of mycelial growth by ether-insoluble fraction.

However, when this fraction was partially ashed and subsequently tested in a similar fashion, the mycelium not only developed normally, but also formed moderate numbers of sporangia of the thraustothecoid type exclusively. On complete ashing, both normal growth and normal production of achlyoid sporangia occurred. Therefore, the alcohol-soluble fraction (1) retained some of the achlyoid-sporangium-inhibiting substance, and (2) contained some presumably organic compound which greatly decreased the extent of the vegetative growth.

b. *Ether-soluble fraction*.—When the ether-soluble fraction was tested in a 25 cc. aqueous solution, the mycelial growth and sporangium development of *T. primoachlya* were completely inhibited. When the ash of the fraction was assayed in 25 cc. of water, growth was normal, and achlyoid sporangia developed in relatively large numbers. When acid ether was used for extraction, there was no perceptible change in results from those appearing in neutral ether, although basic ether eliminated the inhibitory effect. Thus, the ether-soluble fraction contains a substance which inhibits vegetative growth very markedly.

c. *Ether-insoluble fraction*.—When 25 cc. of an aqueous solution of the ether-insoluble fraction was assayed, three unusual responses of the mycelium of

T. primoachlya were evident: (a) abnormally extensive vegetative growth (fig. 4 C), (b) inhibition of the formation of achlyoid sporangia, and (c) frequently, a premature development of oogonia. The increased vegetative growth was noticeable not only in the mycelium extending from the hemp seed but also throughout the solution, where the encysted swarmspores gave rise to extremely long, tenuous, branched, and intertwining hyphae. This growth-promoting substance, in addition to the inhibitory one, is not associated with the auxins, since in concentrations from 1:1 to 1:125, it brought about no distinct curvature of decapitated *Avena* coleoptiles. The thraustothecoid sporangia, slightly smaller in size than those formed in pure water, generally appeared in moderate numbers, and not in dense clusters, but intermittently along the hyphae. Although normally oogonia do not appear until the mycelium is about five days old, in several cultures large numbers developed after about 48 hours.

Investigations on the influence of the staling material on other species.—The mycelia of *Achlya dubia* Coker, *A. flagellata*, *D. achlyoides*, *Saprolegnia* sp., *T. clavata*, and *T. unisporma* were grown at 25°C. in 25 cc. aqueous solutions of the ether-soluble and ether-insoluble fractions of the staling material of *T. primoachlya*. In all cases, the solution of the ether-soluble fraction completely inhibited vegetative growth, whereas that of the ether-insoluble fraction augmented it (fig. 5). The solutions of the ether-insoluble fraction affected the formation of sporangia not only of *T. primoachlya* and *D. achlyoides*, in which achlyoid sporangia never developed, but also of *A. flagellata* and *A. dubia*, in which in addition to the characteristic achlyoid sporangia many atypical ones appeared. In the latter category were: (1) those sporangia which never entirely delimited their spore initials and never dehisced; (2) those in which, although spore development was never completed, dehiscence of the papilla occurred and sometimes was followed by partial expulsion of the sporangium contents; (3) those which had irregular masses of spores near their apices instead of the regular hollow spheres; and (4) those which had part of the spore mass expelled and part retained within. Although these thraustothecoid-like sporangia were quite rare in the mycelium of *A. flagellata*, they did definitely occur. The sporangia of *T. clavata* in the latter solutions were normal, except that the great majority were formed on the surface of the medium.

Thus, the active staling principle of *T. primoachlya* inhibited the development of typical achlyoid sporangia not only in that species but also in *A. flagellata*, *A. dubia*, and *D. achlyoides*.

DISCUSSION.—That the staling products of *T. primoachlya* and other species can inhibit the formation of achlyoid sporangia in *T. primoachlya* and *D. achlyoides* is definite. Although the exact nature of the active principle has not yet been determined, several of its properties are known. Its organic character is reasonably certain because of its destruction by complete ashing, although it is also relatively in-

Fig. 5. Graph, showing the influence of the ether-insoluble fraction on the mycelial growth of seven different species of the Saprolegniaceae. (A, control; B, with ether-insoluble fraction.)

soluble in both ether and alcohol, relatively soluble in water, and resistant to prolonged heating. Its action does not become effective until a threshold concentration is attained, a process the rate of which is greatly hastened by increased oxygen tension. Furthermore, this active compound is not formed only by *T. primoachlya* and *D. achlyoides*, but is a component of the metabolic excretions of other fungi, such as *T. clavata*, *T. unisperma*, etc. In this connection, it is remarkable that its action can be imitated, although not equaled, by some ammonium salts.

The staling products of *T. primoachlya* also contain two compounds which control the vegetative growth not only of that species but also of many of the other Saprolegniaceae. One, soluble in ether and alcohol, greatly inhibits the rate and extent of mycelial development; the other, soluble in water but insoluble in ether and alcohol, markedly increases the rate and extent of vegetative growth. These two substances similarly must reach a threshold concentration before their properties become visibly effective.

The understanding of the mechanism causing the change in sporangia in *T. primoachlya* and *D. achlyoides* makes possible the establishment of the true taxonomic position of the two species. They are unusual in that under normal environmental conditions their genetic constitution can produce in large numbers two types of sporangia, each of which is characteristic of a separate genus. However, since the achlyoid sporangia are inhibited much more readily than those of the other type, the present classification is doubtless the correct one. Nevertheless, that such species are aberrant is obvious, although whether they are the primitive ancestors of the typical modern genera or the results of intergeneric matings is still a matter of speculation.

The fact that the asexual characters of different genera can be altered by physical or chemical components of the environment offers evidence of the very close phylogenetic relationship of the genera of the Saprolegniaceae. Since *Achlya flagellata*, which is characterized by the formation of achlyoid sporangia alone, as reported in the literature and verified by

the writer, can produce sporangia which dehiscence in a manner typical of the genus *Thraustotheca*, the protoplasm of that species must contain some latent characters that associate it with the genus *Thraustotheca*.

Further evidence for this close relationship of the genera appears in the following observations. (1) When *T. clavata* and *Dictyuchus* sp. were grown on hemp seeds in 50 cc. volumes of water at 95°F., many of the sporangia formed papillae of dehiscence at their apices as the spores within were being delimited (cf. Weston, 1918, p. 170). However, these papillae, resembling exactly those functioning in the sporangia of the species of either *Saprolegnia* or *Achlya*, were non-functional, for the sporangia dehiscence each in its normal manner, i.e., in *Thraustotheca*, by an irregular rupture of the external wall, and in *Dictyuchus*, by emergence of single zoospores from their individual cells. (2) When *Achlya* sp. was grown on hemp seeds in 50 cc. of a 0.001 per cent solution of the dye Bismark Brown, the spores in most of the sporangia were not discharged, but remained immotile and germinated *in situ* by the formation of either short vegetative hyphae or short hyphae at the end of which were borne tiny sporangia. This behavior is clearly that of the genus *Aplanes* as originally defined by de Bary (1888). (3) When a sporangium of *Saprolegnia* sp. developed in a hanging-drop of redistilled water at 10°C., the zoospores after emergence behaved in a manner typical not of that genus but of the genus *Protoachlya* (Coker, 1923), in that most of them were sluggish and formed an irregular clump at the sporangial mouth. (4) Under normal conditions, *T. primoachlya* and *T. unisperma* were observed to develop at rare intervals dictyuchoid sporangia, in which the spore initial walls fused with each other and with the outer sporangial wall, and in which the zoospores emerged individually.

In addition, Lechmere (1910, 1911), Collins (1920) and others have reported variations within a species growing in a normal environment which

further illustrate the tendency of the asexual characters of one genus to resemble those of another.

The foregoing observations indicate that under certain environmental conditions the asexual characters of one genus may change so as to resemble those of another, a situation which can take place only if the genera concerned are closely related phylogenetically. This is particularly true in a group such as the Saprolegniaceae, in which the genera are separated by their asexual characters. This close association is further corroborated by the very fact that species do exist which normally have two types of sporangia, each characteristic of a different genus.

SUMMARY

Three species of the Saprolegniaceae are recognized which have typically two methods of sporangium dehiscence, each of which is representative of a different genus: *Thraustotheca primoachlya*, *Diclyuchus achlyoides*, and *T. bispora*. Investigations on *T. primoachlya* and *D. achlyoides*, which produce achlyoid sporangia at first, indicate that some component of the staling material is capable of inhibiting the formation of the achlyoid sporangia. This active staling principle, which is not restricted to the foregoing two fungi but occurs in many others, must attain a certain threshold concentration before its

effect becomes evident. This principle, organic in nature, is probably not an ammonium compound, although ammonia is excreted in relatively large amounts and has some effects in common.

The mycelium of *T. primoachlya* showed responses to extracts of the staling material additional to the one of inhibition of achlyoid-sporangium-formation: (a) both an abnormally extensive vegetative growth and frequently a premature development of oogonia caused by the ether-insoluble fraction, and (b) inhibition of growth and of sporangium formation caused by the ether-soluble fraction. These effects were not restricted to the mycelia of *T. primoachlya* and *D. achlyoides*, but were apparent in the mycelia of other members of the Saprolegniaceae.

From the foregoing results the conclusions are drawn (1) that the successive production of sporangia of *T. primoachlya* and *D. achlyoides* is partly controlled by the environment; (2) that those species with two types of sporangial dehiscence are probably classified correctly; and (3) that the genera concerned are very closely related phylogenetically.

FREEZABLE WATER CONTENT AND THE OXYGEN RESPIRATION IN WHEAT AND RYE GRAIN AT DIFFERENT STAGES OF RIPENING¹

Harold G. Shirk

SHIRK AND Appleman (1940) have shown that a close parallelism exists between the freezable water content and the oxygen respiration of mature wheat when the tissue colloids are in equilibrium with different amounts of imbibed total water. The purpose of the present investigation was to examine the type of relationship between the respiration and total natural water content and between the respiration and freezable water content in cereal grains during growth and ripening of the grain, using immature grain containing different amounts of total natural water.

Fig. 1. The oxygen respiration and water relations of Leapland wheat at different stages of ripening calculated on the fresh weight basis. The height of the columns in the lower section indicates total water, the solid portions unfreezable water, and the shaded portions freezable water as percentage of the fresh weight.

EXPERIMENTAL PROCEDURE AND METHODS.—The wheat and rye grain samples were obtained from plots grown on the University Farm. On each sampling date 90 to 100 heads of grain were brought im-

¹ Received for publication August 8, 1941.

Scientific Paper A2. Contribution No. 1719 of the Maryland Agricultural Experiment Station (Department of Botany).

mediately to the laboratory. Duplicate respiration samples were taken by removing four kernels from the central portion of each head. Two kernels were used in each of the duplicate samples, making a total of 180 to 200 kernels in each respirometer. The time required for sampling varied from 75 minutes for the

Fig. 2. The oxygen respiration and water relations of Leapland wheat at different stages of development calculated on the dry weight basis. The columns in the lower section indicate unfreezable water.

green milk stage grain to 15 minutes for the preparation of the more mature grain samples. After the respiration samples were weighed and placed in the respirometers, a second sampling was made of the same lot of heads removing four additional grains from the middle of each spike. After completing the duplicate respiration determinations, the grain in the respirometers was added to the second sampling of grain, mixed, and portions thereof were taken for triplicate freezable water determinations and duplicate total water determinations.

The total water determinations were made by drying at 80°C. in a vacuum oven under 3 to 4 cm. pressure. The total water content is expressed as percentage of the fresh weight.

The freezable and unfreezable water fractions were determined by the heat of fusion procedure described in detail by Greathouse (1935) with slight modifications as previously described by the author (1940). The freezable and unfreezable water data

are calculated on the fresh and dry weight bases as well as percentage of the total natural water.

The Warburg manometer and respirometer used in this investigation have been described in detail by Shirk and Appleman (1940). The samples were left in the respirometers at 28°C . for a 30-minute temperature equilibration period after which the respiration was measured for one hour. The results are expressed as cubic millimeters of oxygen at standard temperature and pressure taken up in one hour per gram fresh weight and per gram dry weight.

RESULTS.—*Wheat*.—Leapland² wheat grown in 1939 and 1940 was used for this portion of the investigation. The experiments with both wheat and rye from the 1940 crop were a repetition of those with the 1939 crop except for the freezing temperature. The results with the two crops were so similar that only the data from the 1940 study are presented in detail. The first sample of the 1940 wheat crop was collected about one week following pollination of the flowers at which time the total water content was 77.5 per cent of the fresh weight. Samples were taken at one-, two-, and three-day intervals until the total water content of the grain was about 29 per cent. The oxygen respiration intensity and the water relations of developing and ripening wheat are presented in table 1 and in figures 1 and 2.

In figure 1 the water fractions and the oxygen taken up by the grain in one hour are calculated on the fresh weight basis. Because of the difficulty sometimes encountered in interpreting free and bound water data calculated on the fresh weight basis when the total water content is a variable throughout the experimental period, the data were also calculated on the dry weight basis as shown in figure 2.

The respiratory activity is very high in the young grain. The peak of activity is reached eleven or twelve days after pollination followed by a rather sharp decline which becomes more gradual as the grain matures. The total water content (as indicated by the total heights of the columns in the lower section of figure 1) decreased rather gradually throughout the 1940 experimental period. The progressive decrease of the percentage of total water is paralleled very closely by the freezable water content, indicating that the loss of free water accounts for a large measure of the total water loss. There is a close parallelism between the freezable water content and the respiration intensity, calculated both on fresh and dry weight bases as shown in the upper sections of figures 1 and 2, except during the earlier stages of grain development. The histographic representation of the water fractions calculated as percentage of fresh weight in the lower section of figure 1 shows the gradual changing of the freezable-unfreezable water equilibrium shifting from a ratio of 5.23 (5.23 parts freezable water to 1 part of unfreezable water) in the first sample to a ratio of 0.50 for the last sample. Approximately 84 per cent of

²Leapland wheat is a natural selection of Leap wheat developed at the Maryland Agricultural Experiment Station.

the total water present in the first sample of wheat grain was free water or freezable at -25°C . As development and ripening took place a smaller percentage of the total water was freezable, until finally when the grain had 29 per cent total water only approximately one-third of it was freezable.

The tendency for one gram dry matter to associate less unfreezable water as ripening of wheat grain takes place is rather interesting, indicating either

Fig. 3. The oxygen respiration and freezable water of Leapland wheat grain at different natural total water contents. The 1939 freezable water samples were frozen at -15°C ; the 1940 samples were frozen at -25°C .

an increase of hydrophilic colloids or a higher water-binding capacity of the colloids present in the grain immediately following their formation.

In figure 3 are presented the respiration and freezable water data from both the 1939 and 1940 wheat studies. The respiration intensity and the freezable water per gram dry weight are plotted against the total water content. In the 1939 study the freezable water samples were frozen at -15°C , instead of -25°C , as in the 1940 study. The conditions for the respiration and total water measurements were otherwise the same for the two years. The respiration results are surprisingly similar for the two years' work. A comparison of the freezable water curves for the two years shows that they coincide very closely, indicating that no more water was frozen from the 1940 wheat grain when frozen at -25°C , than from similar grain grown in 1939 and frozen at -15°C . The biocolloidal system of wheat at the different stages of ripening and development included in this investigation is evidently in equilibrium with a given amount of unfreezable water at -15°C , which

cannot be frozen by lowering the temperature to -25°C .

The parallelism between the fall of the respiration intensity and the decrease of freezable water as wheat grain ripens is again easily recognized from the curves in figure 3. The curves formed by plotting the respiration and freezable water against total water of the immature grain resemble logarithmic type, similar to the curves formed by plotting respi-

study during the same early phase of kernel development.

A comparison of the oxygen respiration intensity in tables 1 and 2 for the wheat and rye at approxi-

Fig. 4. The oxygen respiration and water relations of rye grain at different stages of development calculated on the fresh weight basis. The height of the columns in the lower section indicates total water, the solid portions unfreezable water, and the shaded portions freezable water.

ration and freezable water against the imbibed total water of mature wheat grain (1940).

Rye.—The Abbruzzi rye used in this experiment was collected at one-, two-, and three-day intervals during the ripening and maturation of the grain. The first sampling during the 1940 study was taken about one week following pollination, at which time the total water content was 75.5 per cent of the fresh weight. The water relations and oxygen respiration of rye grain at different stages of development and ripening during the 1940 season are presented in table 2 and shown graphically in figures 4 and 5.

From the upper sections in figures 4 and 5 it is apparent that there is a close parallelism between the declining rate of oxygen respiration and the decreasing amount of freezable water as rye grain develops and ripens. This parallelism is equally apparent whether calculated on the dry weight or on the fresh weight basis. The time rate of decline for both the total water and freezable water was more gradual and less rapid for the 1940 crop of rye during the earlier stages of development than for the 1940 crop of wheat during the same period. Samplings during the 1939 rye study were not started early enough to make a similar comparison with the 1939 wheat

Fig. 5. The oxygen respiration and water relations of rye grain at different stages of development calculated on the dry weight basis.

mately equal stages of development shows the oxidative processes of the wheat grain to be somewhat higher than in rye. The tendency for one gram of dry matter to associate less unfreezable water as the rye ripens is shown in the lower section of figure 5, with the drift of this tendency not as pronounced as with the wheat. The freezable-unfreezable water equilibrium as presented in the lower section of figure 4 shifted from a ratio of 5.5 parts freezable to 1 part unfreezable water for the first sampling to 0.60 for the last sampling.

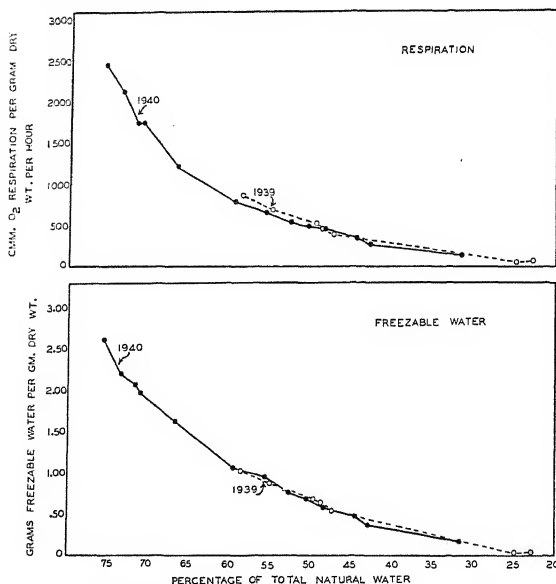

Fig. 6. The oxygen respiration and freezable water of Abbruzzi rye grain at different natural total water contents. The 1939 freezable water samples were frozen at -15°C ; the 1940 samples were frozen at -25°C .

In figure 6 are presented the results for the 1939 and 1940 rye studies. The data in this graph are plotted against the total water content instead of time as in figures 4 and 5. The respiration and total water were determined by the same procedures in the two studies, but the freezable water samples in the 1939 study were frozen at $-15^{\circ}\text{C}.$, and the 1940 samples at $-25^{\circ}\text{C}.$

From the freezable water data plotted in the lower section of figure 6 it is evident that no more water was frozen at $-25^{\circ}\text{C}.$ in the 1940 rye than at $-15^{\circ}\text{C}.$ in the 1939 rye.

The closely duplicated curves formed by plotting the 1939 and 1940 respiration rates against the total water are closely paralleled by the similarly duplicated freezable water curves as plotted in the lower section of figure 6.

SUMMARY

The Warburg manometer was used to measure the oxygen respiration of rye and wheat grain at different stages of ripening in relation to the freezable water content and total natural water. The freezable water was measured by the heat of fusion technique; the 1939 rye and wheat samples were frozen at $-15^{\circ}\text{C}.$ and the 1940 samples at $-25^{\circ}\text{C}.$

Comparing the average results from the two years' work with immature rye and wheat, there was no apparent difference between the amounts of water freezable from the respective 1939 grain samples when frozen at $-15^{\circ}\text{C}.$ and the 1940 samples frozen at $-25^{\circ}\text{C}.$

As the young green grain of rye and wheat developed and ripened, the free water in the grain decreased. At the same time, there was a similar time rate decrease in the amount of oxygen taken up in one hour per gram fresh weight or per gram dry weight of grain which paralleled the time rate decrease of the freezable water in each case. This same close relationship was shown when the respiration data and freezable water results were plotted against the total water instead of time. The descending and paralleling respiration and freezable water curves for immature rye and wheat when plotted against time or against total water were very closely duplicated in the 1939 and 1940 studies.

Both wheat and rye showed a tendency to associate less bound water per gram of dry grain as development and ripening took place. This tendency which was most pronounced in ripening wheat grain was however relatively small when compared with the loss of free water during the same time; so that there resulted a large shifting of the free-bound water equilibrium.

THE PHOTODYNAMIC ACTION OF NEUTRAL RED ON ROOT TIPS OF BARLEY SEEDLINGS. PART II. ABNORMALITIES OF CELLS AND TISSUE¹

Elizabeth Knight Patterson

A CYTOLOGICAL study was made of the photodynamic action of neutral red on the root tips of seedlings of *Hordeum vulgare*. A previous paper, Part I (Patterson, 1941), describes the methods used and the resulting fall in the frequency of cell division. Three groups of roots were used: Group E, the experimental roots, which were immersed in a 1:75,000 solution of neutral red and irradiated with sunlight for one hour; Group NRC, the neutral red controls, which were kept in the dye solution in the dark;

¹ Received for publication August 21, 1941.

Parts I and II comprise a dissertation presented to the faculty of Bryn Mawr College in partial fulfillment of the requirements for the degree of Doctor of Philosophy. The subject of this investigation was suggested by the late Dr. David H. Tennent and the author is glad to take this opportunity to express her appreciation for his valuable advice and criticism during the course of the work. She is also grateful to Dr. William L. Doyle and Dr. Walter C. Michels for their invaluable assistance in the preparation of the photomicrographs. The author wishes to thank Dr. Mary S. Gardiner and the Department of Biology of Bryn Mawr College for the laboratory facilities placed at her disposal.

Group SC, the sun controls, which were put in distilled water and irradiated with direct sunlight simultaneously with Group E. In one experiment another group was added, Group DC, the dark controls, which were kept in distilled water in the dark. All groups were grown in the dark, and the dye solution in Groups E and NRC was replaced with distilled water one hour after irradiation.

Counts of mitoses in sections of the experimental roots fixed at various intervals after irradiation (0-70 hours) showed that there was a sharp decrease in the frequency of cell division, the roots becoming mitosis-free about seven hours after irradiation. The neutral red controls maintained a high frequency of cell division, whereas the sun controls showed a 40 per cent decrease in the number of divisions present. After twenty hours sections of both sun and neutral red controls had normal numbers of cell divisions. No abnormalities of nuclear division were seen in the control roots. The roots irradiated in neutral red solution and fixed 20 to 70 hours after irradiation ex-

hibited three types of response to the photodynamic injury: (1) division started again, (2) the roots continued to mature, and (3) the cells died progressively inward toward the center of the root.

A study of the division cycle in the experimental roots suggested that, after an initial decline in the number of cells entering division, there was a group of cells retarded in interphase which went through

greater in the cells on one side of the root than on the other. In material fixed two hours after the end of irradiation a continuation of this reaction was seen. The small vacuoles coalesced, and four hours after irradiation the lower meristem cells contained only a few large vacuoles (fig. 2). These vacuoles were filled with a precipitate in some cases and in others with a homogeneous mass of unstained mate-

Fig. 1-8. The progress of vacuolization in barley roots irradiated with sunlight in a 1:75,000 solution of neutral red and fixed at various intervals after irradiation. Photomicrographs were taken with an Argus camera using 35 mm. Panatomic-X film and enlarging. Longitudinal 6-micron paraffin sections were stained by Heidenhain's iron haematoxylin procedure with the exception of the several Feulgen preparation as noted. division, after which a gradual falling off took place until no new cells started division. In one experiment an arrest in metaphase also occurred but the injury to these cells was so great that death resulted.

VACUOLIZATION AND MATURING OF CELLS AND TISSUE.—Sections of barley roots that had been irradiated in neutral red and fixed immediately after the end of irradiation could not be distinguished from the controls as far as their general appearance was concerned. The cytoplasm in the lower meristem cells was dense, and there were no visible vacuoles even in the dermatogen. In the tips of roots fixed one hour after irradiation the cells in the dermatogen showed many small vacuoles (fig. 1). Their occurrence was

rial. This may or may not have been neutral red. The vacuolization was so extensive in the nine-hour material that the sections appeared lacy (fig. 3). The cytoplasm of the meristem cells of all the controls remained dense throughout the experiments. Figure 4 from the nine-hour neutral red control and figure 5 from the nine-hour sun control serve as examples of the whole series of controls.

A study of sections of material (Group E) fixed twenty-three hours after irradiation in dye solution (fig. 6-7) showed that all of the cells of the dermatogen and periblem and many of the cells of the plerome contained one large vacuole. The cell walls were thickened, the cytoplasm limited to a narrow

band close to the walls and surrounding the nuclei. The nuclei had assumed the small and compact appearance of those normally found in the zone of elongation of the root. Such cells will be referred to below as "maturing." In the irradiated roots acid fixation was less apt to produce a vacuole in the nucleus than in similar cells in normal roots. The chromatin lay in an abnormally heavily staining net often in an eccentric position in the nucleus. The net masked the nucleoli which were small, again like those in the zone of elongation. There was no sign of any cell division in this twenty-three-hour material and the meristematic character of the root was, therefore, entirely lost. The whole picture suggested that, following arrest of division, the cells had matured. The main difference between these cells and those normally found in the zone of elongation was that the longitudinal dimensions of the latter were usually greater than their transverse measurements. The cells in the tip in the twenty-three-hour material were approximately equal in length and breadth. The mature character of the central row of cells was striking. At this stage the tracheids with spiral thickenings did not extend farther toward the tip in the irradiated than in the control roots.

Pekarek (1927) described in detail a similar premature aging of the root tissue of *Vicia faba* after treatment with X-rays. He states that one day after irradiation the cells had the same appearance as they would have had in the normal root in the region approximately two millimeters behind the initial zone. A study of the appearance and measurement of the size of the resting nuclei added data to his observations on maturation due to vacuolization of the roots. Pekarek's work confirmed that of Koernicke (1905) on the effect of X-irradiation on growth of roots. Koernicke pointed out that this premature aging of the meristem is a typical phenomenon in young plants that are inhibited in growth. The non-specific nature of the effect was also evident from the present experiments in which injured roots of both neutral red and sun control groups showed maturing cells at the tip.

When the vacuolization reaction was very severe, death of the cells followed. This was the case with the stronger intensities of sunlight, and with the most sensitive root tips. In experiment I, material fixed seven hours after irradiation in dye solution showed many dead cells in the dermatogen, more on one side of the root than the other. Greater injury occurred on the side of the root toward the sun. From this time on, every group of experimental roots fixed showed varying numbers of dead cells in the sections of one or more of the roots. Sections of four roots fixed twenty-three hours after irradiation are shown in figure 8. The dark lines on the edge of the sections were caused by dead cells that had stained intensely with haematoxylin. The roots that were approximately straight had about equal numbers of dead cells on both sides; the bent roots had more dead cells on the concave side. This bending will be discussed in detail later.

Many sections were found with three or more rows of dead cells on the periphery. This was especially characteristic of the material in experiments II, III, and IV (see Patterson, 1941, tables 1 and 3). Here dead cells appeared in the roots fixed as early as two hours after irradiation in dye solution. A section of such a root in which part of the dermatogen is torn off is given in figure 9. The normal condition of the neutral red control for this time is shown in figure 10. In the irradiated roots fixed a day later, death of the cells had progressed inward to such a degree that only the cells of theplerome remained alive. The cytoplasm in these cells exhibited that peculiar granular appearance often indicating a stage in the process of degeneration. The chromatin in the dividing cells (all abnormal) stained intensely with haematoxylin, that in the resting cells very faintly. Roots in this condition did not recover, and the cell divisions arrested originally could be seen until the root completely degenerated. This severe reaction was particularly characteristic of the material in experiment IV.

Division reappeared in thirteen (24 per cent) of the fifty-five roots examined twenty or more hours after irradiation in neutral red. The mitotic figures were normal in every respect (fig. 13, 14). In the cells that first started to divide after the mitosis-free interval, the group of chromosomes was often pushed to one side of the cell, or compressed in the center of the cell due to the presence of large vacuoles (fig. 14). This was especially true of divisions in the periblem. Such roots when allowed to grow for a period of twenty-two or more hours before sectioning were found to have root tips of normal character in which the cytoplasm of the cells was dense. In many cases divisions reappeared after a bending of the root occurred. Dead cells were always seen on the inner side of the bend (fig. 12, 15, and 19). It seems justifiable to assume that the root had been injured and that if division had not been completely arrested, it at least had been curtailed. In figure 13 new divisions are shown on the right of the central row of cells. These latter cells showed signs of injury, being stained intensely with haematoxylin (fig. 12). The divisions were, therefore, on the convex side of the root.

Further evidence of a previous injury to the older roots that showed division figures is given in figure 11. The row of dead cells on the periphery of the root was being sloughed off and the outer row of cells of the periblem was taking their place. These cells now had the columnar shape of cells of the dermatogen, and the new mucilaginous coat that they secreted may be seen (arrow) as a grey line between them and the black dead cells.

Koernicke (1905) in describing the effect of Ra irradiation on the growth of roots of *Vicia faba* seedlings noted that the cells of the root cap, as well as the original cells of the dermatogen, died and were sloughed off as the root resumed normal growth. Cells from the periblem then formed the outer layer of root cells and root hair formation did not occur.

Fig. 9-24. Death and bending of roots and formation of branch roots.—Fig. 9. Edge of section of root tip fixed two hours after irradiation in experiment IV. Dermatogen cells dead, some sloughed off, and outer rows of periblem cells dead or dying; granular appearance of cytoplasm of inner periblem cells abnormal. Arrow points to a pseudoamitosis in which cytoplasmic bridge on one side is causing a deviation of upper daughter nucleus. $\times 260$.—Fig. 10. Comparable area in section of corresponding neutral red control root; vacuoles smaller and cytoplasm more homogeneous than in irradiated root; divisions normal; no dead cells. $\times 260$.—Fig. 11. Edge of section of root fixed $44\frac{1}{2}$ hours after irradiation in experiment II; normal division resumed; row of dead cells (black) on periphery sloughing off along with its heavy mucilaginous outer layer (grey). Outer row of periblem cells taking their place now have columnar shape of dermatogen cells. Arrow points to grey line of new mucilaginous layer secreted by these cells. $\times 260$.—Fig. 12. Section of root fixed twenty-five hours after irradiation in experiment III; number of dead cells lining concave side of bend greater in region of elongation than at tip. Few dead cells on convex side where tension caused rupture of outer cell row. Periblem cells on convex side swollen; plerome displaced toward concave side at tip; dead cells in central row. $\times 60$.—Fig. 13. Region in figure 12 enclosed in square given in higher magnification. Normal divisions on convex side of root; cell walls thickened and large vacuoles still present in many cells. $\times 260$.—Fig. 14. Another section of root given in figures 12 and 13. Chromosomes in prophase and in normal metaphase plate are pushed to side of cell by vacuoles. $\times 1,000$.—Fig. 15. Section of root fixed twenty-eight hours after irradiation in experiment IV; root bent into loop; tip growing downward roughly perpendicular to plane of figure. More dead cells on concave than on convex side of bend, periblem cells swollen both sides. $\times 27$.—Fig. 16. Cross section in higher magnification of tip of root in figure 15; dead cells outline root; some cells of cap dead. Many divisions present especially in plerome which lies in an eccentric position toward side of root with greater number of dead cells. $\times 116$.—Fig. 17. Another section of root in figures 15 and 16; Feulgen preparation; periblem cells on concave side of root swollen. Arrow points to branch root

PHOTOTROPIC RESPONSE.—Roots of barley seedlings that had been irradiated in sunlight for one hour in a 1:75,000 solution of neutral red, and subsequently kept in the dark for twenty hours or more, exhibited a marked ageotropic bending. During the first hour of the period in the dark the roots remained in the neutral red solution, which was replaced by distilled water for the remainder of the period. The roots bent sharply upward in the direction from which the light had come. In some roots growth was permanently arrested at this stage, in others division began again and the root grew downward. This resulted in the formation of loops or U's. Out of eighty-three controls kept in the dark in a solution of neutral red of the same concentration, only one showed any signs of bending. Root tips irradiated in sunlight for one hour in distilled water behaved normally. The experimental arrangement was such that geotropic bending was hindered since the roots were growing in water only 4–5 mm. in depth.

In a growth experiment roots were irradiated in neutral red solution and left for seventy hours after irradiation. Observation of the whole roots at the end of this period showed that out of forty-four, eighteen or 41 per cent exhibited ageotropic bending, while the control roots were all straight. Six of the bent roots continued to grow, but growth was arrested in the remaining twelve (see table 6, Part I, Patterson, 1941).

The data from roots fixed in the interval 20 to 70 hours after irradiation (table 3, Part I) showed that in fifty-five irradiated roots, twenty-three or 42 per cent bent upward. Sections revealed that cell divisions were present in only eleven of these. Only those roots that had more dead cells on one side than on the other were bent. This is evident in figure 8, which shows four roots in which division was arrested. The tip of one of these roots, given in higher magnification in figures 6 and 7, shows the mature nature of the cells. The section in figure 19 is of a root in which a few cell divisions had started. The tip of this root, shown in figure 20 in a higher magnification, reveals an odd pattern of the dead cells. The cells of the periblem in the row next to the dead cells were exceedingly swollen, especially in the transverse direction. Even when there were dead cells in the plerome, divisions were present in adjacent cells. Another section of a bent root (fig. 12) shows the pattern of dead cells characteristic of the majority of roots showing bending. The dead cells extended along the concave

side of the root, the number of rows being greater in the region of elongation than at the tip. A few dead cells were seen on the convex side. The tension here must have been so great that the outer row of cells was ruptured. This was found in all the bent roots. Comparison of cells of the periblem of the root represented in figure 17 with those of the root shown in figure 12 demonstrated that in the former they were more swollen on the concave side of the root, in the latter on the convex side. Another section of the same root as that used in making the Feulgen preparation of figure 17 is shown after staining with haematoxylin in figure 15. In every root examined, however, dead cells occurred on the concave side of the bend. It, therefore, seems reasonable to assume that the bending of the roots was caused either by a contraction, or a lack of elongation of one side of the root due to the dead cells. That side must have faced the sun so that the cells were killed by the photodynamic action of the neutral red.

As mentioned before, new cell divisions began in the central cylinder on the convex side of the root. This served to increase the curvature of the root and eventually produced a loop (fig. 15). The tip of this root is bent downward in a direction roughly perpendicular to the plane of the figure. This was, therefore, cut in cross section and is shown in figure 16 in higher magnification. Dead cells could be seen outlining the root, and some of the cells of the root cap were also dead. Many divisions were seen, especially in the plerome which was in an eccentric position, lying toward the side of the root with the greater number of dead cells. This shift of position may have been caused by a contraction of the dying cells on one side of the root while a simultaneous elongation of the cells on the opposite side was taking place. Again the frequency of division may also have been greater on the convex side. In all the roots containing more dead cells on one side, the plerome was displaced toward that side at the tip of the root due to contraction of the dead cells (fig. 12).

Metzner (1923) found that a positive phototropism could be induced in the roots of wheat seedlings by growing them in non-toxic dilute solutions of erythrosin (1:20,000–1:50,000) and rose bengal (1:500,000). In distilled water the roots exhibited only their normal geotropic bending when exposed to light. He distinguished two degrees of response which occurred, depending on the intensity of the light and the concentration of the dye used. In "pas-

forming on convex side of main root. $\times 50$.—Fig. 18. Branch root in figure 17 shown in higher magnification; giant nucleus belongs to cell in a vessel. $\times 260$.—Fig. 19. ^c Included in count of cells with bridges.

sive Krümmung" the roots bent very sharply toward the light (50 "K" frosted metal filament lamp at 25 cm., 1:50,000 erythrosin), while in "active Krümmung" (lamp at 40 cm., 1:500,000 erythrosin) the bending was more gradual. Metzner attributed the response in the case of "passive Krümmung" to an irreversible injury to the epidermal cells on the side of the root toward the light. He could see macroscopically that the root soon became stained red on one side, only dead cells taking up the acid dye. These dead cells could not elongate as did the underlying uninjured cells to which they were firmly connected. Metzner believed that the resulting bending was, therefore, purely mechanical in origin, hence "passive Krümmung." The bending continued until the roots were growing directly toward the light. Metzner explained that, since the root was then shaded by the root cap, the meristem cells were no longer injured and the root continued to grow. He also mentions that the tension on the shaded side of the root was often great enough to cause tearing of the epidermal cells. This was frequently seen in sections of bent roots in the present work.

In Metzner's "active Krümmung," the bending is less sharp and again the growth of the irradiated side falls behind that of the shaded side. But here Metzner believes that the oxidation in the cells facing the light merely influences the velocity of their growth. The bending started in the zone of elongation and, according to Metzner, corresponded exactly to that seen in other tropic reactions. An anatomical study showed that the cells on the concave side were still fully turgid, and Metzner could not recognize any visible staining of these cells. Microtome sections showed no injury to nuclei, and normal cell divisions were seen in the pericycle of the

bending zone. Root hairs were sometimes shorter on the irradiated than on the shaded side of the root.

The results from the present cytological study (using a basic dye that freely entered the cells) agreed completely with Metzner's findings (with an acid dye) in the case of his "passive Krümmung." However, all the roots exhibited a greater degree of injury than that shown in "active Krümmung." Possibly with more dilute dye solutions and less intense light, the latter reaction could be obtained with neutral red. Roots were found that exhibited only slight bending, but in them growth was arrested and the cells were maturing.

Blum and Scott (1933), after repeating Metzner's experiments, concluded "that Metzner's types simply represent different degrees of the same process" (p. 527). They were of the opinion that the phototropic orientation was accomplished by a greater elongation of the cells on the shaded side than on the illuminated side of the zone of active growth. The possibility was also mentioned that with roots in dye solutions, the photochemical reaction may only serve to alter the permeability of the growing cells to the acid dye, the side of the root taking up more dye being delayed in growth. The bending of the roots observed in the present experiments was very similar to that shown in the figures in the paper by Blum and Scott.

Blum and Scott found that wheat roots in dye solution in the dark exhibited delayed growth and unoriented bending similar to that described by Boas and Merckenschlager (1925). These latter investigators found that roots from barley grains, germinated in the dark in Petri dishes containing solutions of eosin (1:3,000 to 1:640,000), grew in all directions, some directly upward. This ageotropic growth was not exhibited by grains germinated in neutral

red (1:3,000 to 1:12,000). These experiments were verified and extended by a number of other investigators whose work has been reviewed by Boysen-Jensen (1934). Boysen-Jensen found that roots exhibiting this type of ageotropic behavior contained no growth substance in their tips.

In the present experiments, only one case of bending was seen in roots grown in the dark after two hours' immersion in neutral red (1:75,000). The injury to the irradiated roots was so great that the bending could only be compared with Metzner's "passive Krümmung," due to unilateral death of cells. No determination of the presence of growth substances was made.

FORMATION OF BRANCH ROOTS.—Study of sections of material fixed 20 to 70 hours after irradiation in a solution of neutral red revealed that one to four branch roots were formed in eight out of the thirteen roots in which new cell divisions were visible (Patterson, 1941, table 3). These branch roots usually developed in the bend of the main root and extended toward its convex side, *i.e.*, away from the dead cells. The arrow points to such a root in the Feulgen preparation shown in figure 17. This branch root is shown in higher magnification in figure 18. The large nucleus to the right of the branch root was a giant nucleus of a cell in a vessel. Two branch roots were starting to form in the bend of the root shown in the section in figure 21. That these groups of cells actually represented embryonic branch roots is illustrated by a section of a root fixed seventy hours after irradiation (fig. 22). The root can be seen emerging from the stele opposite a xylem strand. Organization of the cells into plerome and periblem regions is shown in figure 23 which is a higher magnification of figure 22. The endodermis of the main root was being pushed out ahead of the branch root, and it was about to rupture. Every group of meristematic tissue seen in the mature region of the roots occurred in connection with the pericycle, and even the smallest groups

showed the organization characteristic of branch root formation (see Patterson, 1941, fig. 2).

Some relatively straight roots were found in which branch roots had developed close to the tip. Such a root is shown in figure 24. Two branch roots were developing 2.1 and 2.8 mm. from the apex of the main root. The meristematic cells of the latter showed no division, and there were many dead cells in the plerome. This root was similar in appearance to the onion roots described as occurring after hormone treatment by Levan (1939). These roots after growing four to six days in dilutions (1,000 to .001 ppm.) of indole acetic acid showed a decrease in the number of divisions in the apical meristem until none were seen. The tip often atrophied. Simultaneously many dividing cells appeared in the exterior layers (pericycle) of the stele. Sometimes these cells were uniformly dispersed, but usually they were grouped and gave rise to lateral roots. Levan also described dividing cortical cells, the chromosome complement of which had often been doubled or quadrupled. No such cells were seen in the irradiated barley roots. Swellings above the meristem due to the sudden enlarging of the cortical cells as described by Levan after hormone treatment were seen in the present experiments in occasional control and experimental roots that were well supplied with root hairs.

A control root (sun) fixed 34½ hours after irradiation showed formation of two branch roots. The main root tip was injured, showing many dead cells. Sections of a control root (neutral red) fixed 44 hours after irradiation showed an abortive attempt at the formation of a branch root. The group of meristematic cells were all dead. The main root was bent and there was no division visible in the tip, the cells being mature. All control roots with normal meristematic tissue in their tips showed no sign of formation of branch roots.

In order to find out if branch roots appeared normally under the conditions of these experiments,

Fig. 25-44. Abnormalities in the division figure.—Fig. 25. Immediately after irradiation; anaphase has Y shaped bridge formed by the fusion of ends of daughter chromosomes; this bridge and bridge at right of figure probably resulted in a rupture of the upper group of chromosomes into two parts. $\times 1,100$.—Fig. 27. One hour after irradiation; metaphase chromosomes split and loosely coiled; no spindle is present, chromosomes scattered in the cytoplasm. $\times 1,340$.—Fig. 28. One hour after irradiation; anaphase with many chromosomal bridges. $\times 1,100$.—Fig. 29. One hour after irradiation; anaphase with clockwise deviation of about 60 degrees of lower daughter chromosome group; lateral bridge causing this now broken. $\times 1,050$.—Fig. 30. One hour after irradiation; anaphase in which a single chromosome has adhered to one of opposite group and been pulled away from its normal position. $\times 1,000$.—Fig. 31. Two hours after irradiation; ana-

roots were allowed to grow in water in the dark for ten days. No branch roots appeared. But some seedlings were left in a covered Petri dish and the roots became dry in spots and were moldy. In seven days two branch roots had appeared about 50 mm. back from the tip of one root that had become dry.

The data from these experiments were too meagre to permit an interpretation.² Three possible explanations suggest themselves; the formation of branch roots may have been a response to (1) failure of growth in the tip due to injuries, (2) activity of wound hormones, (3) cessation of formation of growth substance in the tip and, therefore, no inhibition to the formation of branch roots.

Pekarek (1927) reported the presence of groups of meristematic tissue in the middle of the zone of elongation of X-rayed roots of *Vicia faba* fixed three to four days after irradiation. Although at first glance these groups resembled the "Röntgen tumors" seen by Komuro (1925), Pekarek traced their origin to the pericycle and postulated that they represented a premature formation of accessory roots.

The very early branch roots seen in the material from the present experiments exhibited a striking resemblance to the meristematic groups in Pekarek's figures.

ABNORMALITIES IN THE DIVISION FIGURE.—Coincident with the decline in the frequency of nuclear division, a number of abnormalities of division were observed. These were similar in all respects to those

² Patton and Nebel (1940) reported increased formation of branch root initials in cut onion roots after treatment with methylcholanthrene. Elongation, respiration, and dipeptidase activity were decreased in excised corn roots. In the present work, it was found that barley roots treated with neutral red (1:20,000 non-irradiated) showed normal dipeptidase content, whereas irradiated roots (1:75,000 neutral red) showed a marked decrease in enzyme. Patton and Nebel obtained no photodynamic effect of carcinogenic substances using corn roots. Neutral red (Patterson, 1941) was also found to be photodynamically inactive on corn roots.

phase with bridges; several chromosomes in a group separated from one daughter plate. $\times 1,000$.—Fig. 32. One hour after irradiation; chromosomal bridge in anaphase causing complete separation of group of chromosomes from main group in lower daughter plate. $\times 1,165$.—Fig. 33. One hour after irradiation; anaphase with many chromosomal bridges causing separation of daughter chromosomes into three groups resembling those of a tripolar figure. $\times 1,500$.—Fig. 34. Two hours after irradiation; anaphase in which the many chromosomal bridges have caused a separation of daughter chromosomes into four groups giving the appearance of a tetrapolar figure. $\times 1,100$.—Fig. 35. One hour after irradiation; partial pycnosis in anaphase; group of chromosomes form pycnotic mass at equator of division figure, while some of the daughter chromosomes have reached poles; bridges join these with the central mass. $\times 1,200$.—Fig. 36. Two hours after irradiation; partial pycnosis of anaphase chromosomes. $\times 1,100$.—Fig. 37. Two hours after irradiation; late anaphase with strong bridges involving several chromosomes. $\times 1,100$.—Fig. 38. One hour after irradiation; bridge in early telophase; chromosome shows beaded appearance; remaining chromosomes in lower plate are in next section. $\times 1,000$.—Fig. 39. Two hours after irradiation; telophase in which chromosomes in bridge as well as in daughter nuclei are in the spireme condition. $\times 1,000$.—Fig. 40. Three hours after irradiation; pseudoamitosis with nuclei in resting condition and a chromosome in the connecting stalk. Vacuoles prevent normal formation of cell plate. $\times 1,500$.—Fig. 41. Thirty-four and one-half hours after irradiation in experiment IV; Feulgen preparation; pseudoamitosis with stalk containing cytoplasm but very little chromatin. $\times 1,500$.—Fig. 42. Twenty-eight hours after irradiation in experiment IV; Feulgen preparation; late telophase pseudoamitosis with thin chromatic stalk to one side of figure causing deviation of upper daughter nucleus, part of which lies below plane of photograph. $\times 2,350$.—Fig. 43. Twenty-eight hours after irradiation in experiment IV; Feulgen preparation; upper cell contains bridge in telophase involving many chromosomes and probably leading to a pseudoamitosis with unilateral retraction, i.e., more chromatin occurring in upper daughter nucleus than lower. Binucleate cell below must have resulted from pseudoamitosis with thin stalk on right side of figure causing deviation of upper nucleus. $\times 1,500$.—Fig. 44. Nine hours after irradiation; two large dermatogen cells are probably didiploid giant cells arising from pseudoamitosis with bilateral retraction of chromatin due to strong bridges; note large vacuoles. $\times 525$.

described by other workers in tissue subjected to a variety of injurious stimuli. In so far as the abnormalities all occurred in the period before the mitosis-free interval, they may be designated as belonging to the period of "primary effect" of Politzer (1934) or Alberti and Politzer (1923). New divisions, however, were starting during this interval, and abnormalities in these cells should be compared with the "S-mitoses" of Pekarek (1927). This investigator classified abnormal divisions ("P-mitoses") under "primary effect" when the nuclei were in division at the time of X-irradiation, and under "secondary effect" ("S-mitoses") when they were in interphase during irradiation.

In the present work it was difficult, if not impossible, to determine whether a cell was in division at the time of irradiation. The dye probably remained in the cells of the root tips so that the stimulus lasted over a period of time longer than in the case of X-irradiation. The abnormalities appearing immediately after irradiation with sunlight were the same as those appearing later.

Table 1 gives a summary of the abnormalities found in the roots irradiated in a 1:75,000 solution of neutral red for one hour in sunlight. The pro-phases appeared to be normal in all the material and were not included in the table. The data were taken from experiment I except as otherwise noted. No abnormalities of the degree recorded here were seen in any of the controls.

The frequency of cell division in root tips fixed immediately after irradiation remained high. Abnormalities appeared in divisions near the periphery of the root. A typical pycnotic metaphase in a cell of the dermatogen lying about .5 mm. up from the tip is shown in figure 25. The individual chromosomes cannot be distinguished in the densely staining mass from which their ends project. This pycnosis is the same as that described by Alberti and Politzer (1923) in X-rayed corneas of salamander larvae. In

the irradiated barley roots it occurred in 3 per cent of the metaphases and was the only abnormality of this stage seen immediately after irradiation. Eighteen per cent of the anaphases were abnormal, half of these occurring in cells of the dermatogen. The ends of the daughter chromosomes were fused, forming such strong bridges that during the anaphase movement part of the entire group of chromosomes at one pole was dragged away from the rest (fig. 26, center cell; note Y-shaped bridge). Thus it might be said that the presence of these bridges had caused a separation of the chromosomes in the normally compact daughter plate. This could be called a partial deviation (Alberti and Politzer, 1923, p. 94) in that a portion of the daughter group of chromosomes was pulled away from its normal orientation by the chromosomal bridge. (This phenomenon is further illustrated in figures 29-34 from material fixed one and two hours after irradiation.) Three per cent of the telophases had bridges, and a pseudoamitosis was present with an incomplete cell plate. The fact that seven binucleate cells were found, four in the dermatogen, would seem to indicate either that the formation of the cell plate had been affected, or that earlier pseudoamitoses had a stalk-thinning (Stielverdünnung) end stage (Politzer, 1934) which resulted in a binucleate cell.

Material fixed one hour after irradiation showed a much higher percentage of abnormality of division. Aberrant mitoses were scattered throughout the root tip. Forty-four per cent of the metaphases were abnormal. Half of these were pycnotic and the other half had split, coiled chromosomes scattered in the cell (fig. 27). This latter phenomenon was described by Marquardt (1938) as occurring in somatic mitoses in the root tips of *Scilla campanulata* after treatment with soft X-rays. In the present experiments, it might be possible that cells exhibiting this failure of spindle formation were in interphase at the time of irradiation.³ Their occurrence was much less frequent in the material fixed later in experiment I. In roots fixed two hours after irradiation in experiment IV, 81 per cent of the metaphases were in this condition. Apparently the cycle was stopped here because in the 28- and 34½-hour material these scattered chromosomes were disintegrating. The pycnotic metaphases also disintegrated. This disintegration was not limited to material in experiment IV. In

³ While this manuscript was in the course of preparation, a film was seen, made by Dr. Margaret Lewis, showing dividing tissue culture cells growing in media containing fluorescent substances, one of which was neutral red (1:200,000). Two types of injury to the cells resulted from irradiation by the light used for taking the motion pictures. If a cell was exposed just before anaphase, the chromosomes separated and went to opposite poles, although they frequently stuck to each other forming bridges, resulting often in one daughter nucleus receiving more chromatin than the other. If a cell was exposed before metaphase, the chromosomes lined up on the spindle which then "softened and shortened" finally dissolving and freeing the split, sometimes clumped, chromosomes in the cytoplasm. The cells died when exposed to the photodynamic influence too long.

all the experiments pycnotic metaphases often occurred in cells of the dermatogen that were about to die. The arrest in metaphase was permanent since the cells in which it occurred were dying. Stages of division were seen that resembled the pycnotic metaphases described by Pauli and Politzer (1929) as present in the corneas of salamander larvae after irradiation with cathode rays. In living cells all metaphases continued to anaphases in the present work.

The longer the interval between irradiation and fixation of the root tips, the greater was the percentage of abnormalities in all the stages of division. In experiment I, anaphases were particularly interesting in material fixed one and two hours after irradiation. In sections of this material 50 per cent and 75 per cent, respectively, of the anaphases showed chromosomal bridges (fig. 28). In half of these anaphases the bridges were stronger on one side than on the other so that deviation of the daughter chromosomes occurred (fig. 29, bridge just broken). There must have been an actual adherence of the chromosomes in these bridges. An anaphase in which a single chromosome has been pulled away from its normal position in the daughter group is shown in figure 30. Anaphases can also be seen (fig. 31, 32, 33, 34) in which several chromosomes in a group have been separated from a daughter plate. In every case the bridges instrumental in causing this partial deviation were evident. A cell with two bridges and a separation of the daughter chromosomes into three groups is seen in figure 33. Figures that might easily be confused with tripolar (fig. 33) or tetrapolar (fig. 34) divisions arose in this way. Either only one daughter plate was pulled apart into two groups or both daughter plates were separated.

In some cases partial pycnosis of the anaphase chromosomes was seen. This phenomenon is the same as that described by Alberti and Politzer (1923, p. 98, fig. 14). A group of chromosomes formed a pycnotic mass at the equator, while two small groups of daughter chromosomes were at the poles (fig. 35, 36). Bridges extended between the chromosomes at the poles and the central mass. Patten and Wigoder (1930) gave similar figures ("gummy mitoses") from X-rayed bean root tips. These occurred during the recovery period.

In the present work it was evident that some of the bridges persisted through late anaphase (fig. 37) and telophase (fig. 38). The chromosomes in the bridge in the latter figure showed a beaded appearance. The remaining chromosomes of the lower plate were seen in the next section. The presence of these bridges led to the formation of pseudoamitotic figures. A cell in which the chromosomes in the bridge as well as in the daughter nuclei were in a telophase spireme is shown in figure 39. Sometimes cells were seen with the daughter nuclei in the resting condition but with a chromosome in the bridge (fig. 40). The sections of root tips showed all three types of end stage of pseudoamitosis described by Politzer (1924) as occurring in corneas of salamander larvae

in non-irradiated solutions of neutral red. As seen from table 1 the stalk-thinning (*Steilverdünnung*) end stage was the most common in root tips. A thin stalk connected the two daughter nuclei (fig. 41 and 42, Feulgen preparations). Sometimes chromatic material was present in the stalk (fig. 42); at other times it was composed only of a clear material (fig. 41). The connection between the daughter nuclei became progressively thinner and finally ruptured giving rise to a binucleate cell (fig. 43). Often the connection occurred very much to one side of the cell (fig. 42, part of upper daughter nucleus below plane of photograph; Feulgen preparation). This gave rise to a binucleate cell in which the daughter nuclei showed great deviation from their normal position with reference to each other (fig. 43).

When the bridges involved a great many chromosomes, the other end stages of pseudoamitosis appeared. In cases of unilateral retraction (fig. 43, Feulgen preparation), the daughter nuclei were of unequal size. Sometimes one was chromatin-free. With bilateral retraction, a didiploid giant cell arose (fig. 44). Out of 102 pseudoamitoses observed, 86 per cent showed evidence of stalk-thinning, 7 per cent bilateral retraction, and 7 per cent unilateral retraction. The fact that a number of binucleate cells were found supports these results.

Many of the binucleate cells, however, may have arisen merely because of lack of formation of a cell plate. The cells were often so full of vacuoles that the plate presumably could not be completed. Becker (1929, 1930) found the same types of abnormalities as those described above in onion root tips grown in solutions of methylene blue or neutral red. He reported that the division membrane was frequently partially or completely missing and that binucleate cells were formed. Becker's (1933) observations on the effect of dye solutions on cell division in the stamen hair cells of *Tradescantia virginiana* showed that vacuoles often interfered with formation of the cell plate. Neutral red was found to be injurious only in very concentrated solutions (1:500). The daughter cells were seen to be joined by bright, structureless strands which divided the phragmoplast. Becker (1935) stained these cells vitally with chrysoidin or Bismark Brown and followed the behavior of the spindle. No trace of formation of a cell plate could be observed. The phragmoplast disappeared, leaving a typical binucleate cell.

It may be concluded, therefore, that the photodynamic action of neutral red on the root tips of barley seedlings produced typical abnormalities of nuclear division. These consisted of pycnosis, formation of bridges in anaphase, and pseudoamitosis. The usual end stage of the pseudoamitoses was that of stalk-thinning (*Stielverdünnung*), although asymmetrical and bilateral retraction end stages were observed. Binucleate cells were formed. This material gave evidence that the anaphase bridges were not due to a simple lagging of the chromosomes as described

by Pekarek (1927), but that an actual adherence of their ends had occurred (Politzer, 1934; Marquardt, 1938).

DISCUSSION.—Since the early work on the photodynamic action of fluorescent dyes (v. Tappeiner, 1900) it has been known that irradiation with visible light greatly increased the toxic effect of these dyes. Irradiation of a cell or an organism in a dilute solution of the dye gave results similar to those produced by a concentrated solution of the dye in the dark.⁴

The photodynamic action of neutral red on the eggs of the sea urchin, *Lytechinus variegatus*, has been studied by Tennent (1935, 1938a, b) in the course of an extensive investigation of the photodynamic action of dyes. Solutions of neutral red in sea water (1:150,000) were toxic to cultures irradiated in sunlight three minutes or more.

The wave lengths of light that were effective lay in the blue end of the visible spectrum. Using a General Electric exposure meter and calibrated filters, Tennent (1938a) found that the "threshold for violent surface reaction (blister cytolysis) of *Lytechinus* eggs in neutral red sea water lies at about 2,500 foot candles."

Tennent (1938b) reported that dividing eggs in solutions of neutral red irradiated in sunlight for two to eight minutes completed their division but showed abnormalities characteristic of the primary effect after X-irradiation, i.e., lagging and pycnosis of chromosomes. He states: "It would be possible to make a phase by phase comparison of the photodynamic effect of neutral red on cell division with the phases obtained by Politzer and others after X-ray irradiation" (p. 101).

Comparison of the effect of X-rays with the toxic action of neutral red alone on the corneas of salamander larvae (Politzer, 1934) shows that the abnormalities found before the mitosis-free interval differ in frequency but not in kind. The great difference lies in the fact that mitoses occurring after the mitosis-free interval are completely normal after neutral red, whereas after X-ray treatment abnormalities are seen for weeks. These include fragmentation of the chromosomes, their resultant abnormal distribution, and formation of accessory nuclei.

Similar conclusions result from a comparison of the photodynamic effect of neutral red as found in the present experiments with the effect of X-rays on plant root tips (Pekarek, 1927; Bersa, 1927; Patten and Wigoder, 1930; Marquardt, 1938). Pekarek (1927) gave an exhaustive description of the effect of X-rays on the root tips of *Vicia faba*. The fall in frequency of cell division, maturing of the tissue, formation of branch roots, and occurrence and nature of abnormalities of division before the mitosis-free interval were very similar to the phenomena found due

⁴ It is now clear (see Blum, 1941, page 83) that the mechanism of photodynamic action differs essentially from that of "dark action." But as far as the resulting abnormalities of nuclear division are concerned, the end effect of the two actions seems to be similar.

to the photodynamic action of neutral red.⁵ In the case of X-irradiation, however, new divisions showed typical fragmentation, etc., while they were normal after neutral red.

Bersa (1927) found that the root tips of *Zea mays* were very resistant to the effect of X-irradiation. The frequency of cell division fell slowly reaching a minimum at 24 hours. Even with the largest doses (16 H), no mitosis-free interval was seen. Abnormalities of nuclear division first occurred in material fixed 36 hours after irradiation. They were not so numerous as those described by Pekarek (1927) or Alberti and Politzer (1924). The number of prophase fell, then rose, but otherwise the division cycle was normal.

Every tissue response described as occurring in root tips of barley seedlings that had been irradiated in a 1:75,000 solution of neutral red, has been found in plant material subjected to other stimuli. Therefore in this material the photodynamic action of neutral red is non-specific in character.

SUMMARY

Roots of barley seedlings were irradiated for one hour in sunlight in a 1:75,000 solution of neutral red and subsequently grown in water in the dark. Control roots in dye solution in the dark and control roots irradiated in distilled water showed no abnormalities. Sections of the experimental roots fixed at va-

⁵ A paper by Prescher (1932) on the photodynamic action of eosin on root tips of *Vicia faba* has recently come to the author's attention. Counts of cell divisions were made on roots grown in light in eosin solutions (1:5,000, 1:10,000, 1:25,000, 1:100,000) and on complete sets of controls. The results are in general in agreement with the present work, with the exception that Prescher found no mitosis-free interval, no bridges in anaphase, and no pseudoamitoses. If a concentration of eosin between 1:25,000 and 1:100,000 had been used, these abnormalities might have been observed.

rious intervals after irradiation showed many abnormalities in the cells and tissue. Immediately following irradiation, vacuolization of the dermatogen cells of the root tip set in. Along with a rapid fall in frequency of cell division, the vacuolization reaction spread throughout the meristem region, increasing in intensity so that twenty-three hours after irradiation the entire root tip contained cells typical of the zone of elongation of the root. The root tips were mitosis-free after seven hours.

Roots observed 20 to 70 hours after irradiation in dye solution exhibited marked ageotropic bending. Study of the sections showed that in every case a greater number of dead cells were present on the concave than on the convex side of the root. The side facing the sun was photodynamically injured, and the bending was probably due to a contraction of the dead cells or a greater elongation of the cells which were shaded, or both. Formation of branch roots in the bend of the main roots was often observed. These roots grew toward the convex side of the main root. Instances of this were also found in injured roots of the controls.

The abnormalities in cell division occurring before the mitosis-free interval consisted of pycnosis, formation in anaphase of bridges, and pseudoamitoses. The stalk-thinning end stage of pseudoamitosis was the most frequent, although cases of unilateral and bilateral retraction were seen. These abnormalities, together with the fall in frequency of cell division, maturing of the tissue, and formation of branch roots, are similar to some of the effects found by others after X-irradiation of plant tissue, as well as after other stimuli.

INHIBITORY EFFECTS OF INORGANIC COMPOUNDS ON PHOTOSYNTHESIS IN CHLORELLA¹

Sydney S. Greenfield

WARBURG'S (1919, 1920) demonstration that cyanides affect the dark reactions, and urethanes the light reactions in photosynthesis has been useful in research and theoretical discussions. Since earlier work had shown that inorganic salts were capable of depressing photosynthesis in *Elodea* (Trebois, 1903; Pantanelli, 1903) and other plants (Spoehr, 1926), the present investigation was made to study further the inhibitory effects of several inorganic compounds on photosynthesis in *Chlorella* and to determine, in particular, whether they could separately inhibit the dark and the light reactions. It was thought that the results of this work might provide evidence which would be useful in the study of the mechanism of photosynthesis as well as of the physiological influence of these chemicals.

The present paper reports the effects of excessive concentrations of certain chemical substances, most of which have been demonstrated as necessary in plant nutrition, on the rate of photosynthesis in *Chlorella vulgaris*. The compounds employed include some known to be toxic in very low concentrations and others only effective at much higher concentrations. Sucrose solutions were used to determine which salts act through an osmotic effect and to study this effect. Rates of photosynthesis were measured by means of Warburg manometers. In order to determine the relations of the inhibitors to the light and dark reactions in photosynthesis, inhibition was studied at five light intensities, over a range from where light was the limiting factor to where it was in excess. A preliminary note on some of the results has appeared in *Science* (Greenfield, 1941).

¹ Received for publication March 27, 1941.

The experiments were performed in the laboratory of plant physiology at Columbia University. The author is indebted to Professor Sam F. Trelease for suggestions and criticisms throughout the course of the investigation and the preparation of the manuscript.

MATERIALS AND METHODS.—Tests were made with the unicellular alga *Chlorella vulgaris*, cultured according to the method of Warburg (1919) as modified by Craig and Trelease (1937). Culture flasks of liter volume were used with 300 cc. of the following solution, KNO₃, 0.025 M; MgSO₄, 0.020 M; KH₂PO₄, 0.018 M; FeSO₄, 0.00001 M; K-citrate, 0.00001 M; and 14.2 cc. per liter of a stock solution containing the microtrophic elements boron, copper, manganese, zinc, etc. (Trelease and Trelease, 1935). A mixture of 5 per cent CO₂ in air was continuously bubbled through the culture solutions, and a 300-watt tungsten filament lamp, cooled by a water jacket, was the light source. The flasks were kept 15 cm. from the lamp, where the average light intensity was about 10,000 lux. New cultures were inoculated with 35 million cells from an actively growing culture, and populations of 18 to 25 million cells per cc. were obtained on the fourth day. At this stage of active growth, cells were removed from the cultures for experiments and for new culture inoculation. Cell concentrations were estimated with a haemocytometer.

Since the purpose of this study was to analyze the effects of chemicals caused by their presence during rate measurement and not in culture, it would have been desirable to dissolve the salts in the test buffer. As several salts caused an evolution of gas from the carbonate-bicarbonate buffer selected, this was not feasible, but left the choice of either using another test medium or employing a method of cell treatment and washing prior to suspension in the buffer. After preliminary tests, the latter choice was made, to permit rate measurements of control and treated cells under the uniform external conditions obtainable in the buffer. The method of pretreatment eliminated reactions of the test substances with the suspension medium that might have altered gas solubilities or

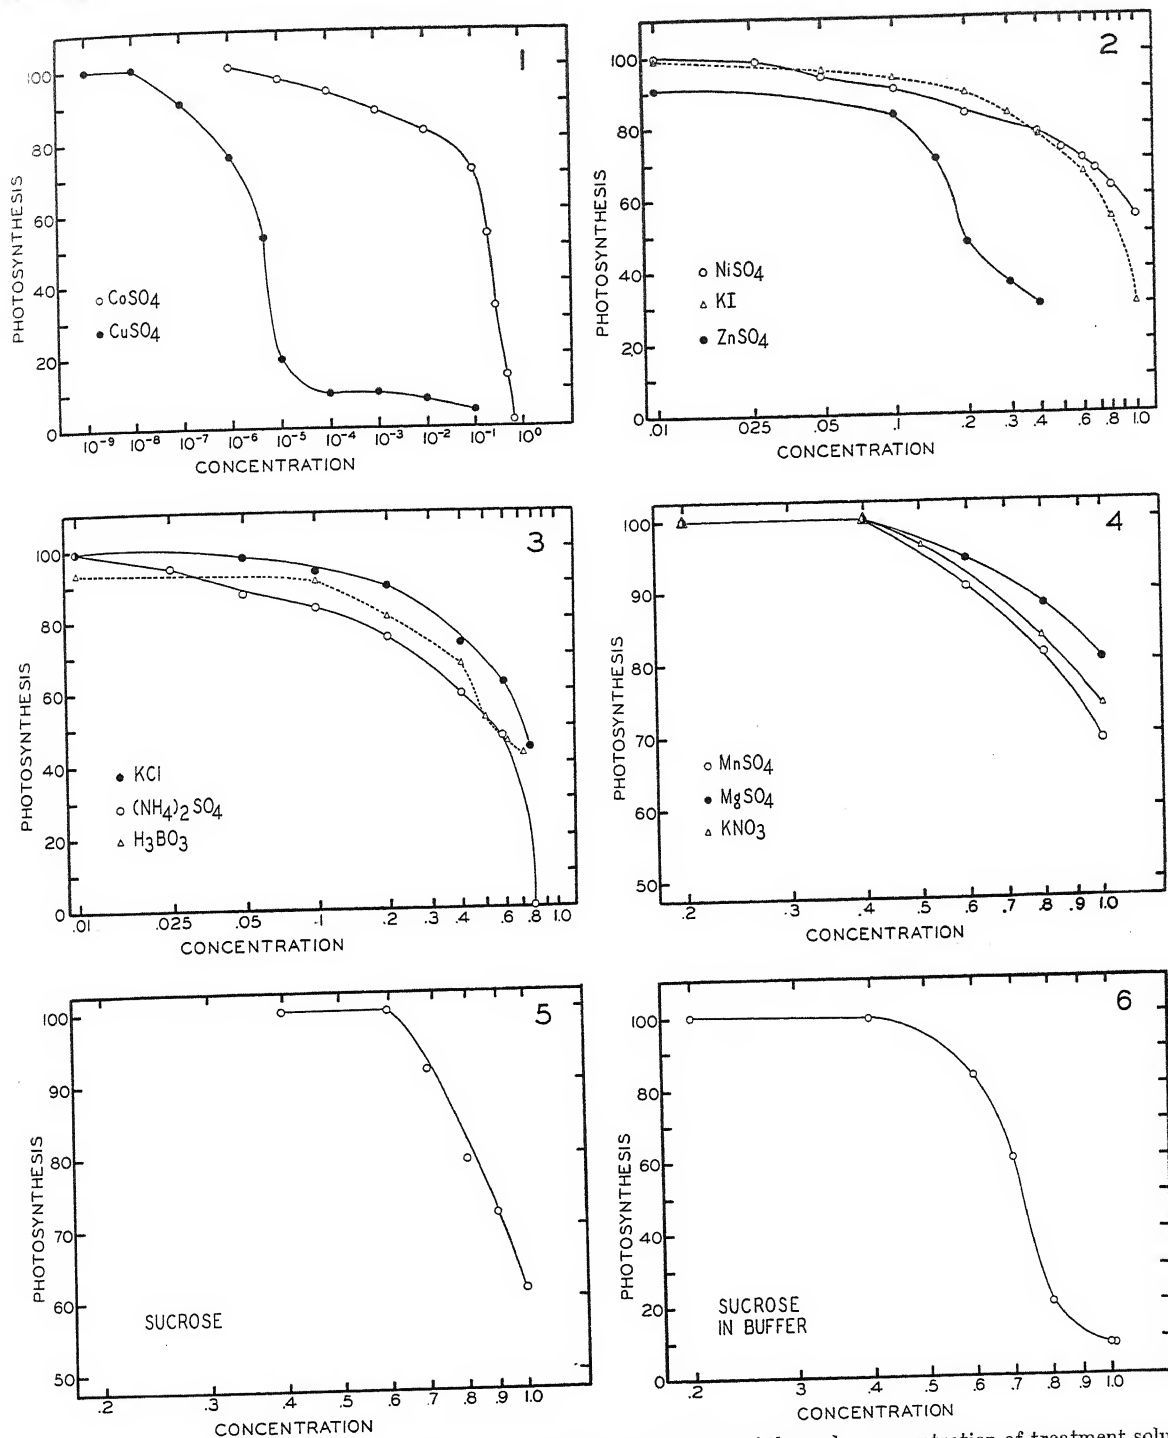

Fig. 1-6. Rates of photosynthesis (percentage of control) as a function of the molar concentration of treatment solution. Logarithmic concentration scale. Light intensity 22,000 lux.

factor, suspensions were kept in the dark during treatment.

The results of these experiments are shown in tables 1 to 3, wherein the rates given are the averages of several determinations. The relationships between rates of treated and untreated cells are plotted

in figures 1-4, using logarithmic scales of concentrations to avoid crowding of points.

The inhibitory effect of CuSO_4 was most pronounced, being evident at the low concentration of 10^{-7} M (fig. 1) and increasing strongly at higher concentrations. Solutions of CoSO_4 (table 1, fig. 1)

[illegible]

effective below the threshold of osmotic pressure inhibition and, therefore, any chemical effect they may have had on the photosynthesis of *Chlorella* could not be detected.

Calculations for all of the substances previously considered (fig. 1-3) showed them to be effective below the point of interference by osmotic pressure, as determined by the experiments with sucrose. They are consequently capable of an inhibition independent of this factor. Although in some cases the curves extend into the region of osmotically active concentrations, they exhibit no secondary drop, such as might be expected. The effect of the withdrawal of water was not observable, since it may have been masked by the chemical inhibition. Although the water content was reduced, it did not become the limiting factor.

Respiration.—The respiratory rates in almost all of these experiments were similar. They are not listed separately, because, although they are sufficiently reliable for correcting the apparent photosynthetic rates, they are less precise than the latter, due to the small readings obtained. The rates averaged about 0.07 c.mm. of O_2 consumed per minute by the standard sample of 35 million cells. At high light intensities the respiration rate was less than 5 per cent of the photosynthetic rate; but, at the lowest light intensities used in experiments described later in this paper, it was as much as 30 per cent. Treatment with high concentrations of $CoSO_4$ and $CuSO_4$ slightly depressed respiration. With 0.8 M and 1.0 M $(NH_4)_2SO_4$, which completely stopped photosynthesis, the respiratory rate was normal. Inhibition of photosynthesis in normally respiring cells was first observed by Bernard (1878), and the observation has been confirmed (Irving, 1911; Spoehr, 1926).

TABLE 4. *Respiration rates (c.mm. O_2 absorbed by 35 million cells per minute) of cells treated with $HgCl_2$. The rates are averages of two or three experiments wherein both light and dark rates were determined with the same cells. Light intensity 22,000 lux.*

$HgCl_2$ molarity	Light rate	Dark rate	Ratio: Light/dark rates
2.5×10^{-5}	0.125	0.065	1.9
5×10^{-5}	0.140	0.070	2.0
10^{-4}	0.155	0.075	1.9
10^{-3}	0.145	0.070	2.1
10^{-2}	0.160	0.050	3.2
10^{-1}	0.075	0.045	1.7

Treatment with concentrations of $HgCl_2$ of 2.5×10^{-5} M or higher completely inhibited photosynthesis, but consumption of oxygen in respiration was observed in the light as well as in the dark. Although other respiratory data are incorporated into the corrected photosynthetic rates, those determined in the experiments with $HgCl_2$ merit separate presentation. Control rates in the light were obviously unobtainable, but in the dark they were about

0.07 c.mm., the same as those of treated cells, in most cases. Table 4 gives the rates in the light and dark for each concentration which completely inhibited photosynthesis.

The respiration rate in the dark was normal except with the two highest concentrations, but in the light the rate was approximately doubled in most cases. Whether this high respiratory rate in the light is normal for illuminated cells, or due to $HgCl_2$ treatment, cannot be determined from these experiments. Poisons are known to accelerate metabolic processes temporarily (Reynolds, 1939), but since photosynthesis is here completely inhibited, it may be the true respiratory rate in the light that is revealed. Van der Pauw (1932) was able to stop photosynthesis in *Horridium* by treatment with 0.002 M KCN and also observed a higher respiration rate in the light than in the dark.

Recent investigations have suggested the presence of a photo-oxidation in the photosynthetic system, since large amounts of carbon dioxide were observed to evolve during the induction period (Gaffron, 1940) and during measurements at injurious light intensities (Myers and Burr, 1940). In the present experiments the rapid oxygen absorption by cells pretreated with $HgCl_2$ might be related to a photo-oxidation, but such an interpretation would be premature with the information now available.

Effects on subsequent culture.—In order to study further the effects of the substances found to inhibit photosynthesis in relation to behavior of cells in culture, to duration of treatment, and to light intensity, a single concentration of each substance was selected. Wherever possible, a concentration was chosen which caused approximately 50 per cent inhibition of photosynthesis at 22,000 lux. In other cases a less depressing concentration had to be selected, below the critically effective osmotic pressure threshold, in order to insure the study of the effect of the substance itself, uncomplicated by the reduction of water content in the cell. These concentrations are indicated in the experiments, and are summarized in table 5:

TABLE 5.

Substance	Concentration reducing photosynthesis to about 50 per cent of the control	Concentration used in subsequent experiments
$CuSO_4$	5×10^{-6}	5×10^{-6}
$CoSO_4$	0.2	0.2
$ZnSO_4$	0.2	0.2
H_3BO_3	0.5	0.5
$(NH_4)_2SO_4$	0.5	0.4
KCl	0.7	0.3
KI	0.8	0.3
$NaSO_4$	1.0	0.4

For each substance an experiment was performed to test the effect of treatment with the selected con

centration on subsequent culture. Cells were treated in the regular manner for twenty minutes and then washed, but instead of being suspended in the buffer, 35 million cells of the treated group were inoculated into 300 cc. of culture solution and an equal number

The effects of treatment with HgCl_2 on subsequent growth were also studied. Three flasks of culture solution were inoculated with 35 million cells of groups treated with distilled water, 10^{-5} M, and 10^{-4} M HgCl_2 , respectively, and were observed for five days. Throughout this period, the group treated with

Fig. 7-8. Rate of photosynthesis (percentage of control) as a function of treatment duration in minutes. Following the treatment, 10 minutes were required for centrifugation and decantation.

of cells treated with distilled water was inoculated into another culture flask. Both were then grown under the standard culture conditions described, and compared daily for five days.

The results of all tests were essentially the same, except for the cells treated with CoSO_4 , where a slightly lower cell count was evident. Cell numbers, greenness, size, and general appearance were similar in cultures inoculated with untreated and treated cells. Thus plants subjected to a treatment which inhibited photosynthesis as much as 50 per cent appeared to grow and reproduce normally when inoculated into a culture solution. The treatment seems to have produced a state wherein there was present in the cell a concentration of the inhibiting substance which affected photosynthesis without causing permanent alteration in the cell systems.

Fig. 9-11. Rate of photosynthesis (c.mm. O_2 per min. per 35 million cells) for treated cells and controls. Light intensities in lux. Both scales logarithmic.

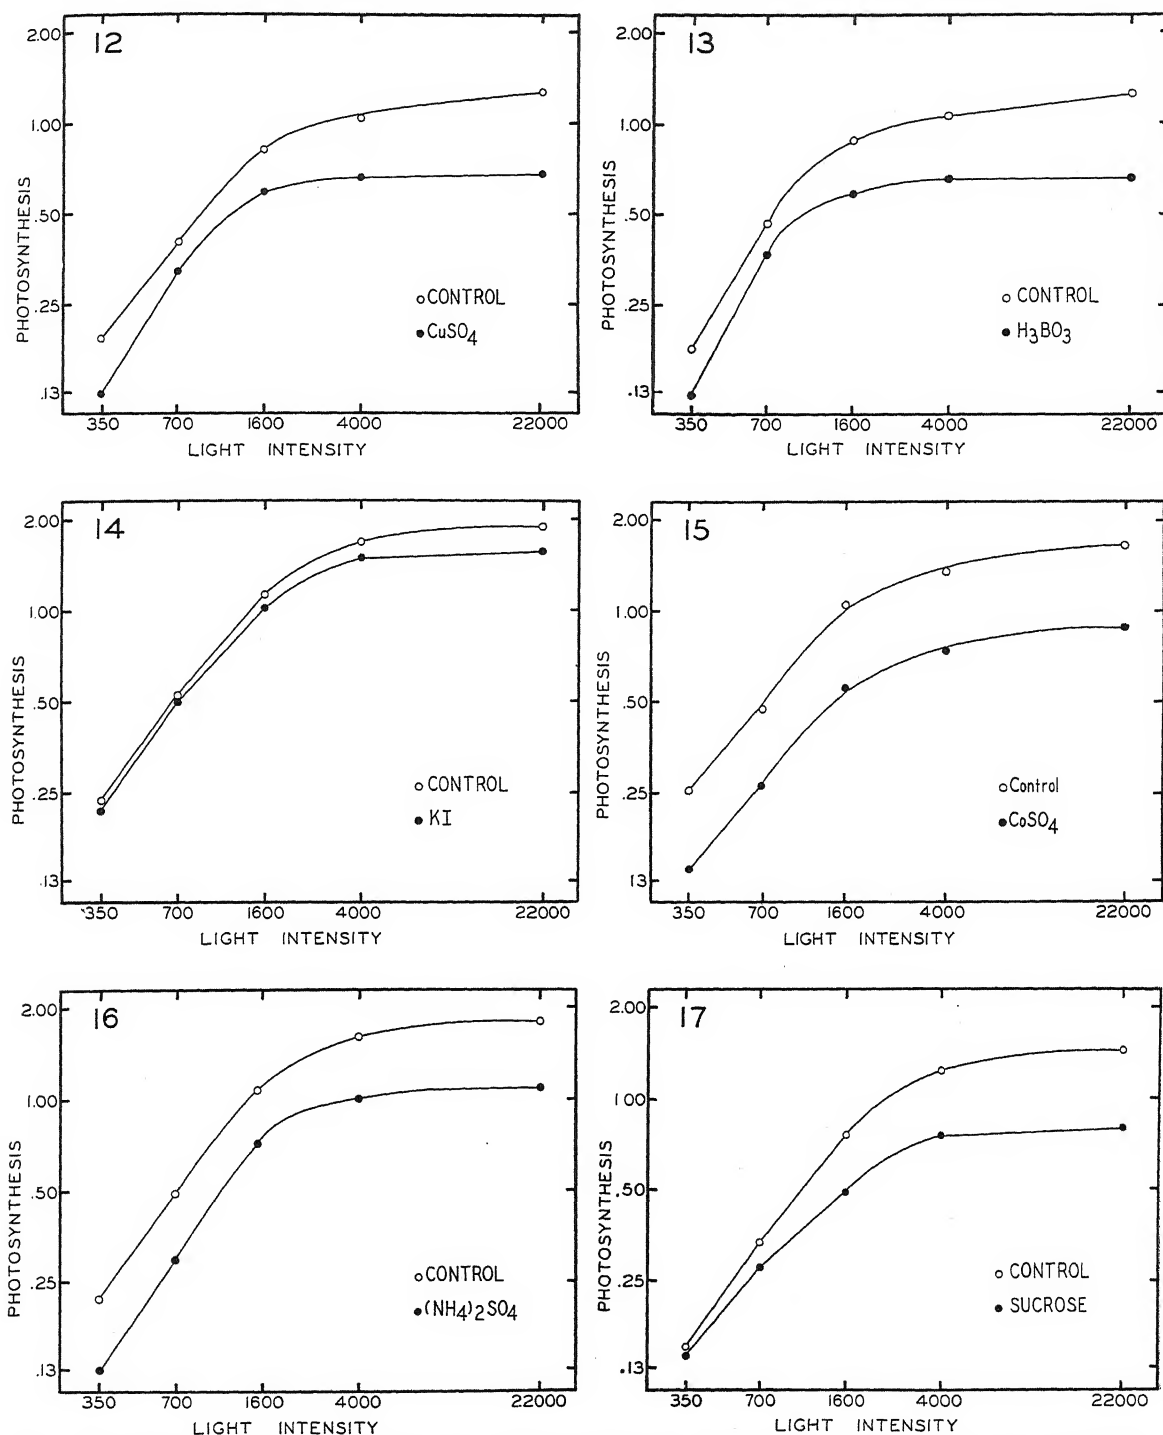

Fig. 12-17. Rate of photosynthesis (c.mm. O_2 per min. per 35 million cells) for treated cells and controls. Light intensities in lux. Both scales logarithmic.

10^{-5} M HgCl_2 grew like the control culture, indicating no residual toxic effect of the treatment. However, the cells treated with 10^{-4} M HgCl_2 were pale green when introduced into the culture solution, and the culture remained pale for three days. During this time the cell population did not appreciably increase,

nor did the chlorophyll return to normal color. On the fourth day, however, the culture was definitely green, and considerable multiplication had occurred. It exhibited normal growth thereafter. The treatment did not kill all the cells, since subsequent growth, although delayed, was evident. HgCl_2 ap-

pears to have stopped photosynthesis temporarily by injuring the cells and destroying some of the chlorophyll. After sufficient time had elapsed for recovery (involving possibly some outward diffusion of the toxic salt) and production of new pigment, the cells functioned normally.

TABLE 6. Rates of photosynthesis (c.mm. O_2 per min. per 35 million cells) at five light intensities, for untreated cells and cells treated with test solutions or in a buffer with sucrose.

Test solution		Light intensity in lux				
		350	700	1,600	4,000	22,000

	Treated	0.130	0.300	0.720	1.005	1.095
Sucrose 0.7 M in buffer	Control	0.153	0.338	0.755	1.230	1.440
	Treated	0.140	0.278	0.490	0.758	0.795

Influence of treatment duration.—Experiments in which the time of treatment was varied were performed with the selected concentration of each inhibitory substance. The time periods used were 2½, 5, 10, 20, 30, and 40 minutes, plus 10 minutes required for centrifugation and decantation of the test solutions. The amount of inhibition is plotted as a function of time of treatment in figures 7 and 8. The results of these tests indicate that the twenty-minute period used in most of the experiments (twenty minutes of treatment plus ten minutes of centrifuging and decanting) was expedient, since the leveling of the curves indicates that a state of equilibrium was reached before the end of the time period chosen (fig. 7, 8). This equilibrium is not a simple penetration equilibrium, since it also involves diffusion activity, following the soaking period, both in the distilled water wash and in the buffer.

The curves for cells treated with $CoSO_4$ and $(NH_4)_2SO_4$ show secondary increases in inhibition after forty minutes' treatment. Not indicated on the curve for $CoSO_4$ tests are values for longer experiments wherein the rate of photosynthesis was reduced to 14 per cent by continuing the treatment for one hour, and stopped completely by extending to three hours. These cells still carried on respiration and showed no abnormal appearance. It is perhaps indicative of like modes of action that the effects

of $CoSO_4$ and $(NH_4)_2SO_4$ are similar in the experiments which follow.

Influence of light intensity.—The rates of photosynthesis of cells treated with inhibitory substances were measured at five light intensities in order to determine their effects on the light and dark reactions. The concept that inhibition of the photochemical or dark reactions may be determined by comparing inhibitory effects at low and at high light intensities has been used by Warburg, Spoehr, Emerson, Arnold, Briggs, and many other investigators. It has been discussed recently in critical reviews by Franck and Gaffron (1941) and by Manning (1938).

The data of the present experiments at various light intensities are given in table 6, wherein the rates recorded are averages of several determinations. In figures 9 to 17 the rates of control and treated groups are plotted as a function of light intensity. Logarithmic scales have been used because they avoid crowding of points at low light intensities and give essentially straight lines for the parts of the curves in the range where light intensity is limiting. [The control curves are similar in type to those

Fig. 18-19. Relative rate of photosynthesis of treated cells (percentage of control rate) as a function of light intensity. Light intensities in lux on logarithmic scale.

of Smith (1937), but they represent different tests and are neither identical with his nor with each other.]

The results may be explained in relation to figure 20, in which the control or normal curve is used as the basis of comparison, and the general types of curves obtained with treated cells are illustrated. The curves are interpreted according to the limiting factor hypothesis of Blackman (1905). Thus, in the normal curve AB the rate of photosynthesis rises with increase in light intensity over the low intensity range, because here light limits, or determines, the rate of the whole process of photosynthesis. But at higher light intensities the curve flattens, since here light is in excess, and some factor controlling the dark reaction limits the rate. In the same sense, at low light intensities the photochemical reaction is limiting, and at high light intensities the dark reaction is limiting.

An inhibition of the dark reaction alone should result in a curve like AED (fig. 20), where inhibition is most evident when the dark reaction determines the rate and diminishes as the limiting factor status of this reaction decreases. The curves of figures 9–11, representing treatment with 0.2 M ZnSO_4 , 0.4 M NiSO_4 , and 0.3 M KCl , resemble AED in figure 20 and indicate that these substances affect only the dark reaction, since the curves of untreated and treated cells are close at low light intensity and diverge as the light intensity increases. This is also illustrated in figure 19, where a continuous drop in relative rates is evident from low to high light intensity for cells treated with ZnSO_4 , NiSO_4 , and KCl . Other studies have shown that the dark reaction may be retarded by heavy water (Craig and Trelease, 1937; Pratt and Trelease, 1938) or by high concentrations of carbon dioxide (Livingston and Franck, 1940).

If a substance affected only the photochemical reaction, greatest inhibition of photosynthesis, as shown by greatest divergence of curves for control and treated cells (as between A and C of curves AB and CEB, fig. 20), would be evident at low light intensities where the photochemical reaction determined the rate, and retardation would become negligible at high light intensities where the dark reaction became limiting and the light reaction was in excess. None of the inorganic substances tested gave a curve like CEB, but phenylurethane in Warburg's (1919) experiments approximated this type.

A substance which retards both photochemical and dark reactions should give a rate curve which resembles the composite curve CED in figure 20. Variations of this curve have been obtained. The effects of 5×10^{-6} M CuSO_4 , 0.5 M H_3BO_3 , and 0.3 M KI may be considered together since they resulted in similar curves (fig. 12, 13, 14). Examination of the curves from 22,000 lux down to 700 lux indicates a convergence and, therefore, an inhibition of the dark reaction; but from 700 lux down to 350 lux the curves diverge, indicating an inhibition of the light reaction. (This is shown also in figure 18, where there is a

drop in relative rate below 700 lux for CuSO_4 and H_3BO_3 tests, and in figure 19 for KI tests.) In figures 12 and 13 the points of closest proximity of control and experimental curves actually lie between 700 and 1,600 lux. These points correspond to the light intensity at which theoretically two separate inhibition curves cross and are resolved into the plotted curve. The curves for cells treated with CuSO_4 , H_3BO_3 , and KI are composites representing chiefly an inhibition of the dark reaction and to a lesser extent an inhibition of the light reaction.

Fig. 20. Diagram of differential inhibition of light reaction and dark reaction. (The normal curve is a composite of all control data plotted on logarithmic scales, and the other curves have been drawn with the same shape.)

Inhibition by 0.2 M CoSO_4 and 0.4 $(\text{NH}_4)_2\text{SO}_4$ results in curves (fig. 15, 16) which are approximately equidistant from the control curve at all light intensities, except that in figure 16 the curves are somewhat closer in the region of 1,600 lux. These curves resemble the composite curve CED in figure 20. In figure 18 it is evident that the amount of inhibition by CoSO_4 was about the same at all light intensities, but for $(\text{NH}_4)_2\text{SO}_4$ there is an indication of least inhibition at 1,600 lux. It may be concluded that CoSO_4 inhibits photosynthesis by retarding both the photochemical and the dark reactions about equally, and that $(\text{NH}_4)_2\text{SO}_4$ approximates this action.

Tests with sucrose solutions, introduced as a basis for determining the osmotic pressure threshold of inhibition, indicated that solutions of KNO_3 , MnSO_4 , and MgSO_4 only inhibited photosynthesis when they were sufficiently concentrated to exert an osmotic effect and lower the water content of the cells. Inhibition by sucrose solutions of high osmotic pressure was studied at various light intensities. Cells were placed in a buffer that contained sucrose in a concentration of 0.7 M. From table 6 and figures 17 and 19 it is clear that the amount of inhibition is reduced at low light intensities and is greatest at light saturation, where the dark reaction determines the rate.

TABLE 7.

Concentration	At 700 lux			At 22,000 lux		
	Control	Treated	Percentage of control	Control	Treated	Percentage of control
KCN						
0.10 M	0.43	0.40	93	1.97	1.55	79
0.20 M	0.43	0.33	78	1.97	0.90	46
Phenylurethane						
0.006 M	0.68	0.49	72	1.69	1.48	87
0.007 M	0.56	0.37	67	1.90	1.50	79

Reduction of water content, therefore, retards the dark reaction and has little or no effect on the light reaction.

Treboux (1903), Pantanelli (1903), Bernbeck (1924), and Dastur (1925) observed a decline in photosynthetic rate with a loss of water and lowered cell turgidity. The retardation of the dark reaction observed in the present experiments with highly concentrated sucrose solutions perhaps indicates that water is involved in the dark reaction; but the possibilities are very complicated, and limitation of water content may serve to increase the concentration of inhibitors within the cell which are capable of affecting the dark reaction, or it may modify colloidal conditions of the cell on which the dark reaction depends.

In order to compare the results obtained by the pretreatment method employed in the present studies with the results obtained by Warburg during treatment, tests were made with solutions of potassium cyanide and phenylurethane. The rates (c.mm. O₂ per min. per 35 million cells) obtained at two light intensities are shown in table 7.

With potassium cyanide treatment, greater inhibition was obtained at high light intensity than at low, indicating a retardation of the dark reaction. Treatment with phenylurethane caused greater inhibition at low light intensity than at high, showing retardation of the photochemical reaction. These observations are in agreement with the results and conclusions of Warburg, and indicate, therefore, the suitability of the pretreatment method employed in these studies.

Little is known concerning the various ways in which the different inhibitors act. The effect of narcotics, like phenylurethane, is generally considered to be dependent upon their adsorption by interfaces in the cell, and their retardation of the photochemical reaction has been interpreted as due to an interference with the energy transfer from the light absorbent to another part of the photosynthetic mechanism (Franck and Gaffron, 1941). Inorganic substances, like CoSO₄ and (NH₄)₂SO₄, which strongly depress the light reaction, and others, such as KI, CuSO₄ and H₃BO₃, which retard it to a lesser extent, may also serve in various ways to bring about a hindrance of energy transfer. It is possible that some of these substances may inactivate the chloro-

phyll, although no visible color changes were observed. Thus, the effect of copper may have been brought about by the formation of copper chlorophyll. The peculiar sensitivity of algae to copper has never been adequately explained. HgCl₂ was observed to destroy chlorophyll and probably halted photosynthesis by this means.

Some of the observed inhibitions of the light reaction may be due to effects on dark reactions which may precede it, such as the absorption of carbon dioxide or the formation of a chlorophyllous carbon dioxide compound investigated by McAlister (1939). In essence this would mean that the actual light reaction would be unaffected by the inhibitor, except for the retardation resulting from interference with the prior dark reaction on which it is dependent. Adequate discussion of these relations is difficult at present, because it is not definitely known whether most or all of the reactions constituting the dark stage precede or follow those of the photochemical stage.

Restriction of the dark stage of the photosynthetic process may be brought about by interference with enzyme systems. Cyanides are known to be specific poisons for organometallic catalysts and are considered to affect the dark reaction by acting on its enzymes. Some of the inhibitors herein found to affect the dark reaction may act in a similar manner. The various salts studied probably affect different specific reactions of the dark stage rather than all reactions involved in this stage, as would be expected of temperature. Since salts of the heavy metals combine with proteins, retardation of the dark chemical stage, the photochemical stage, or both may have been brought about through a combination with the enzymes or other proteins involved. The findings of Emerson and Green (1938), that pH over a wide range had no effect on photosynthesis of *Chlorella*, seem to eliminate this as an influential factor in the inhibition observed in the present investigations. It is perhaps worthy of special emphasis that, although several of the inorganic compounds tested inhibited the dark stage alone and others retarded both dark and photochemical stages in various degrees, none was found which inhibited only the photochemical stage.

The results of the present survey, showing that several additional substances of diverse chemical na-

ture are able to affect the two principal sets of reactions in the photosynthetic process in ways similar to those of cyanides and urethanes, may be of value in further research on photosynthesis. A study of these substances in various combinations may provide other useful evidence by revealing synergisms and antagonisms. Although in their gross effects on the photochemical and dark reactions of photosynthesis the compounds studied constitute a few groups, it is expected that further analysis will show that they differ markedly in their individual mechanisms of action.

SUMMARY

The inhibitory effects of inorganic compounds on photosynthesis in *Chlorella vulgaris* were studied. Cells were suspended in test solutions for about thirty minutes; they were then rinsed with water, and their rates of photosynthesis in a carbonate-bicarbonate buffer were determined by means of Warburg manometers.

In tests at high light intensity very low concentrations of CuSO_4 , CoSO_4 , and HgCl_2 inhibited photosynthesis, but stronger solutions of ZnSO_4 , H_3BO_3 , $(\text{NH}_4)_2\text{SO}_4$, NiSO_4 , KCl , and KI were required to retard the process. The amount of inhibition tended to vary over a rather wide range of

concentrations, but HgCl_2 showed a narrow range between non-effective and completely inhibiting concentrations. The rates of respiration and of subsequent culture growth were not appreciably affected by treatment with concentrations which reduced photosynthesis 50 per cent. MgSO_4 , MnSO_4 , and KNO_3 inhibited photosynthesis only at concentrations wherein the high osmotic pressure of the solutions lowered the rate.

By means of studies at five different light intensities only the dark reaction was found to be retarded by ZnSO_4 , NiSO_4 , and KCl . The effect of CuSO_4 , H_3BO_3 , and KI was mostly a retardation of the dark reaction and a lesser inhibition of the light stage. CoSO_4 and $(\text{NH}_4)_2\text{SO}_4$ depressed both the dark and photochemical stages of photosynthesis about equally. No substance was found which inhibited only the photochemical stage. Decrease in water content, brought about by suspension of cells in sucrose solutions of high osmotic pressure, caused a retardation of the dark reaction only.

Some possible modes of action of these inhibitors are discussed.

STIMULATORY AND TOXIC EFFECTS OF COPPER SPRAYS ON POWDERY MILDEWS¹

C. E. Yarwood

WHILE COPPER is toxic to many fungi at concentrations above 0.01 per cent and is the most widely used of all chemicals for the control of plant diseases, different fungi vary greatly in their sensitivity to it. At concentrations below 0.001 per cent copper is frequently stimulatory, and Steinberg (1939) regards copper as an essential element for several fungi. The literature on the stimulatory effects of copper at low concentrations for fungi which are grown in culture solutions and on the toxic effect of copper on plant parasitic fungi in general is very extensive and cannot be reviewed here.

The writer is not aware of detailed studies of the copper tolerance of powdery mildews, but copper fungicides are successfully used for the control of certain powdery mildews, though sulphur fungicides are generally considered superior (Martin, 1940). The writer (unpublished data) has secured control of several powdery mildews with several copper as well as several sulphur fungicides used as eradicator or protective treatments in field and greenhouse tests. Copper fungicides are especially useful for the control of powdery mildews on such sulphur-sensitive crops as cucurbits. The stimulation of powdery mildews by dosages of copper which are highly toxic to certain other plant disease fungi and even to powdery mildews under certain conditions is, therefore, of interest.

MATERIALS AND METHODS.—A strain of *Erysiphe polygoni* DC. from clover, *Trifolium pratense* L., and another from bean, *Phaseolus vulgaris* L. var. Pinto, were maintained on greenhouse plants. Bean plants were inoculated with the fungus or treated with the test fungicide, or both, when the primary, true, unifoliate leaves had reached about two-thirds full size. Inoculation was accomplished by dusting dry spores or spraying a water suspension of spores on the upper and lower surfaces of the leaves. Infection on the primary leaves was recorded within ten days after inoculation. Because of the heavy infection in the controls in these tests, counting of individual colonies was impractical and fungus development was rated on a relative scale of 0 to 10 in which 0 indicated no mildew mycelium apparent to the unaided eye, and 10 indicated that the leaf surface was entirely covered with mycelium and conidia. In germination tests 100 spores were counted for each treatment for each test.

Bordeaux mixture containing equal parts of $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ and CaO in water was prepared by adding 13 per cent hydrated lime to the specified amount of copper sulphate which had first been diluted with water to approximately spray strength, and the concentration of bordeaux is expressed as the percentage by weight of $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ in the final spray. The cottonseed oil used was a brand of self-

emulsifying oil containing approximately 85 per cent cottonseed oil and 15 per cent of a glyceryl phthallic ester (SEC oil of Röhm and Haas Company, Philadelphia). The cuproside dust contained 10 per cent red copper oxide, 10 per cent ferric oxide, and 80 per cent bentonite and diatomaceous earth (No. 10 copper dust of A. L. Castle, Mountain View). Spraying was done with a De Vilbiss atomizer using 35 pounds air pressure.

In studies of sprays as protective fungicides the plants were first sprayed with the test fungicide, and the film was allowed to dry for several hours before the plants were inoculated. In studies of sprays as eradicator fungicides the plants were first inoculated and the powdery mildew fungus was allowed to develop for several days before the test fungicide was applied. Because of their exposed mycelium most powdery mildews are uniquely adapted to comparative studies of the same chemicals as eradicator and protective fungicides, and powdery mildews have been extensively used in the evaluation of eradicator sprays (Martin and Salmon, 1932).

Different degrees of relative humidity were obtained by means of known concentrations of sulphuric acid in closed chambers, as described by Stevens (1916).

The term stimulation will be used in the broad sense to indicate the response of the organism in those treated units where the growth was greater than in the control units. The basic cause of the increased growth due to copper sprays is not understood. The term toxic is used in the usual sense to indicate that a given treatment reduced the growth of the organism as compared with the control.

RESULTS.—*Effect of copper on the germination of conidia.*—Conidia of clover powdery mildew dusted on the surface of 7 cc. of test solutions in syracuse watch glasses and held for ten hours in diffuse daylight gave the following germination values (average of five tests): water, 42 per cent; 0.1 per cent copper sulphate, 46 per cent; 1 per cent copper sulphate, 31 per cent; 0.1 per cent mercuric chloride, 31 per cent; and 1 per cent mercuric chloride, 4 per cent. These concentrations of copper and mercury are much higher than are tolerated by most parasitic fungi, and the writer believes that the high tolerance of *Erysiphe polygoni* to water solutions of copper and mercury may be related to the ability of the conidia of *Erysiphe polygoni* to germinate without an external supply of water (Yarwood, 1936b).

The presence of moisture may have an important bearing on the stimulatory and toxic action of copper for powdery mildews. The results of five tests averaged in table 1 show that on glass slides the dried deposit from 0.1 per cent bordeaux + 0.1 per cent cottonseed oil was highly toxic when water was added to the slides along with the clover powdery

mildew conidia and the slides incubated at 100 per cent relative humidity. On the other hand, this same deposit was highly stimulatory when the dry slides with dry spores were incubated at 90 per cent relative humidity. Results at 100 per cent relative humidity, but in the absence of free moisture, were intermediate. Similar results were secured in four tests with *Erysiphe polygoni* from bean, but the toxic action on the atomized slides and the stimulatory action on dry slides at 90 per cent relative humidity were less marked than with clover mildew. Similar dosages of bordeaux without cottonseed oil were only slightly stimulatory if at all, and similar dosages of copper in the form of cuprocide dust were toxic in all environments. All three forms of copper were toxic in all environments to barley powdery mildew (*Erysiphe graminis* DC.) in three tests.

Copper sulphate and bordeaux mixture at various dosages were suspended in plain agar containing 2 per cent sucrose and the poured plates of this substrate were dusted with the conidia of bean powdery mildew. In one representative test the percentage germination on sucrose agar containing 0.06 per cent bordeaux was 71 as compared to 50 in the control

plates, and the average length of the germ tubes in the bordeaux plates was 63 microns as compared to 58 in the control plates. In tests in which the germination in the controls was poor the increase of percentage germination and germ tube length due to copper was usually greater.

Effect of bordeaux spray on the development of bean mildew on leaves.—It has been observed on many occasions that, during periods of high light intensity, powdery mildew develops poorly or not at all on the upper surface of inoculated primary unifoliate bean leaves in the greenhouse, though it develops fairly well on the upper surface of secondary trifoliate leaves and excellently on the lower surface of the primary leaves. The nature of this inhibition by light is not understood, but shading the inoculated plants under such conditions usually favors mildew development on the upper surface of primary leaves. Dilute bordeaux mixture also stimulates mildew development under such conditions, and the results of one test illustrating what the writer believes to be the effect of light and dilute bordeaux on mildew development on the upper surface of primary bean leaves are given in table 2. In this test the pro-

fective bordeaux sprays were applied at 2 p.m., August 6, 1941; at 4 p.m. the dry leaves were dusted with dry spores, and the inoculated plants were placed in the test environments. There was considerable alternation between clear weather and high fog during the nine days of this test, and the light intensity was measured with a Weston photometer on five occasions in each environment during the nine-day period. The outdoors reading for each time of observation was considered as 100, and the other values were expressed in relation to this, the average values being given in table 2. The environments chosen for this test were the outdoors and three different greenhouses with various amounts of shading in the form of a whitewash coating. In this test the light intensity in even the darkest environment was somewhat inhibitory to mildew development. It is realized that light was not the only important environmental factor which varied between these four conditions of exposure, but the writer believes it was the principal one responsible for the differences obtained. The amount of mildew for each treatment was estimated at four, seven, and nine days after inoculation. The results, presented in table 2, indicate that dilute bordeaux mixture stimulated the development of bean mildew under each light condition tested.

In the test just reported the plants were inoculated with dry spores and placed immediately in a dry test environment. When similar bordeaux-sprayed plants were inoculated by spraying them with spores in a water suspension and the inoculated plants were held overnight in a moist chamber before being placed on the greenhouse bench, the effect of the bordeaux spray was frequently, but not always, to reduce the mildew development on the sprayed plants to less than that on the control plants. Here, as with spores on slides (table 1), bordeaux mixture was apparently more toxic in the presence of free water than in its absence.

When dilute bordeaux was used as an eradicant spray, it usually reduced the powdery mildew development on the sprayed plants. In table 3 are given results of one representative test of bordeaux as a protective and as an eradicant spray for bean mildew. In such tests it is difficult to choose comparable conditions of treatment for the protective and eradicant sprays, since the conditions chosen are arbitrary

but may markedly influence the results. The importance of moisture as influencing the effects of protective sprays on powdery mildews has been discussed in the previous paragraph. In eradicant treatments, applications of bordeaux mixture and other fungicides were more effective in killing powdery mildew mycelium if the sprayed plants were kept wet for several hours after spraying than if the sprayed plants were dried immediately. It is known that water alone, sprayed at high pressures, is effective in eradicating powdery mildews (Yarwood, 1939a), but this possibility was guarded against in these tests by using low impact pressures in atomizing the plants.

In the tests reported in table 3, one set of plants was inoculated on February 5. At 10 a.m. February 11 these plants and a second set of uninoculated plants of the same age were sprayed with the different fungicides. At 4 p.m. February 11 the second set of plants was inoculated by dusting the plants with conidia. The first set of plants thus served as a test of the eradicant properties of the fungicides and the second set of plants as a test of the same materials as protective fungicides. Only the results with 0.1 per cent bordeaux and 0.1 per cent cottonseed oil are presented in table 3. In this test, which is representative of several tests of this type, leaves treated with 0.1 per cent bordeaux as a protective spray showed more mildew on their upper surfaces than the control leaves, while the same treatment as an eradicant spray killed practically all the mildew on the upper and lower leaf surfaces. Cottonseed oil and bordeaux plus cottonseed oil were also apparently more effective as eradicant sprays than as protective sprays.

The difference between the relative mildew on the upper leaf surface of the controls for the protective and eradicant applications (table 3) is not due to treatment, but is presumably due to differences in the light environment following the February 5 inoculation (for eradication) and the February 11 inoculation (for protection). Such differences have been quite common in successive inoculations. It is only when the environment has been inhibitory to mildew development on the upper leaf surface that copper stimulation of mildew on growing plants has been demonstrated.

On growing plants as well as on slides (table 1) there are important differences between different

TABLE 3. Comparison of eradicant and protective applications of bordeaux spray on the development of bean powdery mildew.

Spray	Protective application		Eradicant application	
	Relative mildew on upper leaf surface	Relative mildew on lower leaf surface	Relative mildew on upper leaf surface	Relative mildew on lower leaf surface

0.1 per cent bordeaux	5	10	0.5	0
0.1 per cent cottonseed oil	0	2.5	1	0.5
0.1 per cent bordeaux + 0.1 per cent cottonseed oil	0	0.5	0	0

forms of copper. No stimulation of powdery mildew has been observed from applications of cuprous oxide, either as pure cuproside or as cuproside dust. Also the cuproside dust has been uniformly more effective as a protective fungicide for powdery mildews than either cuproside or bordeaux when all were compared at the same copper content.

DISCUSSION.—It is commonly believed that non-gaseous fungicides must go into solution in order to be effective in killing fungi. Since most fungus spores apparently require free moisture for their germination, it has been difficult to test the truth of this assumption. However, the conidia of many powdery mildews do not require free moisture for their germination (Yarwood, 1936b) and are, therefore, adapted to such a study.

Tests reported here show that free moisture is not necessary for either the toxic or stimulatory action of copper fungicides for powdery mildews, though the bordeaux mixture used was more toxic in the presence of free water than in its absence. It therefore appears possible that the contact exchange theory of Jenny and Overstreet (1939), as applied to the absorption of nutrient ions by the roots of higher plants, might be applied to the absorption of copper by fungi and might explain how this can occur in the absence of water.

The results presented in this paper might be interpreted to indicate that copper as a plant nutrient was deficient for the powdery mildews studied under the conditions of these experiments. However, many other unusual treatments such as the addition of iron sulphate, potassium permanganate, potassium nitrate, and egg yolk to the culture medium, the treatment of the spores with heat, the use of spores at certain times of the day, and placing the dry spores on the dry leaf surface, may, under certain conditions, also be stimulatory to the conidia of certain powdery mildews (Yarwood, 1936a, 1939b, 1941).

The results presented are principally for *Ery-*

siphe polygoni from bean and clover. Similar tests with *Erysiphe graminis* from barley and with *Erysiphe cichoracearum* DC. from cucumber and cantaloupe have as yet shown no stimulation, but only toxicity, from copper fungicides.

This study tends to emphasize the importance of experimental conditions in studies of fungicides, since it is shown that a given dose of copper may be toxic, neutral, or stimulatory to the powdery mildews studied, depending on environment and other conditions of the tests. A related observation is that of Abe (1930), who found that 0.0004 to 0.006 per cent copper sulphate was stimulatory to *Piricularia oryzae* Br. et Cav. at 28°C. but was not at higher or lower temperatures.

SUMMARY

The conidia of *Erysiphe polygoni* from clover germinated well on the surface of 1 per cent copper sulphate. The dried deposit of 0.1 per cent bordeaux + 0.1 per cent cottonseed oil on glass slides was toxic to conidia of *Erysiphe polygoni* from red clover and bean in water, approximately neutral on dry slides at 100 per cent relative humidity, and stimulatory on dry slides at 90 per cent relative humidity. Copper sulphate or bordeaux added to sucrose agar increased the percentage germination and the length of the germ tubes of bean powdery mildew conidia. When light was inhibitory following inoculation, bean plants sprayed with 0.1 per cent bordeaux frequently showed more mildew development on the upper surface of primary leaves than did unsprayed plants. Bordeaux was more effective as an eradicant spray than as a protective spray for bean mildew, and no mildew stimulation has been observed when bordeaux was used as an eradicant spray.

TRANSPORT OF THIAMIN IN THE TOMATO PLANT¹

James Bonner

It is known that an external supply of thiamin is essential for growth of the isolated tomato root (Robbins and Bartley, 1937; White, 1937), and it may, therefore, be suspected that in the intact plant also thiamin is in some fashion associated with growth. The present paper deals with the production and distribution of thiamin in the tomato plant.

TECHNICAL.—The experiments to be discussed deal with girdled tomato plants. Seeds ("San Jose Canner" of the California Packing Corporation) were germinated in washed river sand having particles between 10 and 20 mesh. When the seedlings were three weeks old they were transferred to similar sand contained in four-inch clay pots. Hoagland's nutrient solution was supplied daily. These plants were used for experiments when they were between five and six weeks old, at which time they were eight to ten inches tall. In two types of experiments use was made of larger plants. These were grown in coarse gravel contained in two-gallon glazed crocks. All plants were greenhouse grown.

Girdling of the stems or petioles was done with a jet of steam directed through a glass nozzle having an orifice 1 mm. in diameter. This treatment appeared to kill, locally, all living elements of the stem. Within a few hours of the treatment the stem collapsed over a distance of approximately 1 cm. Leaves apical to the girdle did not wilt during a period of at least six days.

All plants were dried in a current of air at 60°C., weighed, ground, and assayed for thiamin content by the *Phycomyces* assay (Schopfer and Jung, 1937). Five \pm 0.1 mg. of plant material were weighed into each of a series of 50 cc. Erlenmeyer flasks. Ten cc.

¹ Received for publication September 6, 1941.

Record of this work was done with the cooperation of the Works Progress Administration, O. P. No. 165-1-07-172, Research in Plant Physiology.

This work was in part made possible by the support of Merck and Co., Inc.

of thiamin-free basal medium² was added to each flask, and the flasks were then fitted with cotton plugs, autoclaved for fifteen minutes at 15 lbs. pressure, and inoculated with 0.2 cc. of a suspension of *Phycomyces Blakesleeanus* spores obtained from a standard stock culture. The cultures were incubated for six days at 25°C. in diffuse light, the mycelia removed, washed, dried and weighed. Controls with no added thiamin and with 0.02, 0.04, or 0.08 γ (micrograms) thiamin per flask were run in each experiment. The apparent thiamin per sample was computed on the basis of the controls with supplements of known amounts of thiamin. Table 1 gives the results of an experiment in which dried ground tomato leaf was assayed at three different levels of sample size. The apparent thiamin per sample is a linear function of the sample size for 2.5, 5.0 and 10.0 mg. samples within the accuracy of the determinations. The calculated thiamin per gm. of leaf tissue is hence independent of the sample size within the same limits of error. Table 1 also shows that added thiamin is quantitatively recovered in the presence of 2.5 or 5 mg. samples of dried tomato leaves. The leaves do not then appear to contain substances which interfere with thiamin determination by the *Phycomyces* method. Estimation of the thiamin content of the same material by the thiochrome method gave a mean value of 5.78 γ /gm.³ in close agreement with the mean value of 5.71 γ /gm. obtained in the *Phycomyces* assay.

Design of experiment.—With two exceptions (tables 10 and 11) the experiments discussed below were planned as follows. The plants for the experi-

² 0.5 gm. $MgSO_4 \cdot 7H_2O$, 1.5 gms. KH_2PO_4 , 20 gms. dextrose, 4 gms. recrystallized asparagin, and 1 cc. of microelement stock solution per liter of Pyrex redistilled water. The microelement stock solution contained 50 mg. $Fe_2(SO_4)_3$, 100 mg. $ZnSO_4$, 20 mg. $CuSO_4$, 10 mg. $MnSO_4$, 10 mg. H_3BO_3 and 20 mg. $(NH_4)_2MoO_4$ per liter.

ment were selected for uniformity from about 1.5 times the needed number. The selected plants were then randomized in groups of eight and each treatment of the experiment was carried out on one such group. Each group was harvested as four samples of two plants each. Each sample of two plants was composited, dried, and analyzed in duplicate. The degree of variability in such an arrangement was tested in a uniformity trial with untreated material and table 2 shows the results obtained with respect to dry weight of tops and thiamin assays. The maximum difference in top dry weight between replicate groups of eight plants amounted to 10.5 per cent of the average dry weight per group, while the average difference from the mean was 3.3 per cent. The results of a variance analysis of the assay data of table 2 are given in table 3. It should be noted that the variance of samples (item c of table 3) is significant when tested against the variance associated with duplicate assays (item d of table 3). Therefore, the variation due to sampling is larger than the analytical error in the experiment.

The standard error of a group mean of four samples (each sample consisting of the mean of two assays) is 0.564 as derived from the 16 mean values of table 2, and the standard error of a difference between two such group means would be 0.80. The difference necessary for significance (between two group means) would be 1.70 at the 5 per cent level of probability (15 degrees of freedom) and 2.36 at the 1 per cent level, the latter value representing a difference between the two means of about 10.6 per cent. This is, however, only a minimum value for the difference between two means necessary for significance in an actual experiment since the variability of plants subjected to varying treatments was larger than the variability of untreated plants, as those of table 2. In general, however, a difference between two means of 25–30 per cent or more was found to be significant as can be seen in tables 5, 6, 7, and 8.

DISTRIBUTION OF THIAMIN.—Table 4 shows the concentration of thiamin in various parts of a series of tomato plants 40 cm. tall. Analyses were done on the apical growing point (including leaves less than approximately 4 cm. long), on each leaf, on the stem, and on the roots. There was a marked concentration gradient of thiamin in these tomato plants in the sense that the highest concentration was found in the apex and successively lower concentrations in each successively older leaf. A similar gradient would appear to occur in the stem. Table 4 also gives the calculated total amount of thiamin per leaf or other part. This figure is the product of the dry weight of the part by its thiamin concentration. The amount of thiamin per leaf was small in the young leaves, rose to a maximum at the 8th leaf, and fell to a small amount in the oldest leaf. This distribution of thiamin in the tomato plant, which has been confirmed in four further experiments on a total of sixty-four plants, does not of itself offer any clue as to the precise site of formation of the substance, a question

which formed the subject of the following experiments.

ACCUMULATION OF THIAMIN ABOVE A GIRDLED PORTION OF STEM.—Nine groups of eight plants each were drawn randomly from a selected set of seventy-two plants. One group was harvested at once. The

plants of four further groups were girdled at the second node by the application of a jet of steam. The remaining four groups served as further controls. Twenty-four hours later, one group of girdled plants and one group of control plants were harvested, and this operation was repeated on the second, fourth, and sixth days after girdling. Each control plant was separated into top (above the second node), roots (below the sand level) and stem sample (1 cm. of stem at the second nodes). Each girdled plant was separated into top, root, stem (1 cm.) immediately above the girdle, and stem (1 cm.) immediately below the girdle. The results of the dry weight determinations and thiamin assays on the top and root samples are given in table 5. The total thiamin contained in the tops and in the roots of the control plants increased markedly during the six days of the experiment. In the tops of the girdled plants, total thiamin also increased, although less markedly than in the control plants. In the roots of the girdled plants, however, total thiamin did not increase significantly beyond the amount initially present and, in fact, decreased markedly after the second day.

Table 6 gives the results of dry weight determinations and thiamin assays on the stem sections from the experiment of table 5. It is evident that there was a marked accumulation of thiamin above the girdle and some depletion of thiamin from below the girdle. The accumulation was apparent one day after girdling, and, on a concentration basis, reached its final maximum by the second day. On the basis of the total thiamin per cm. of stem, however (and associated with the swelling of the stem above the girdle), the accumulation continued during the entire six days of the experiment. On the sixth day, the concentration of thiamin in the 1 cm. of stem above the girdle was 2.8 times as great as the concentration in the corresponding portion of stem in the control plants and 3.5 times as high as the concentration in 1 cm. of stem below the girdle. The total amount of thiamin in 1 cm. of stem above the girdle was 4.8 times as great as the amount in the corresponding portion of control stem and 12.2 times as great as the amount in 1 cm. of stem below the girdle. The results of this experiment, which were confirmed in four similar experiments, suggest that thiamin may be normally transported in living elements of the stem.

ACCUMULATION OF THIAMIN BELOW A GIRDLED PORTION OF STEM.—In this experiment stems of tomato plants were girdled between the mature leaves and the young rapidly growing leaves. Each plant was arbitrarily divided into an apex, possessing leaves less than approximately 3 cm. long, and a portion with three mature leaves. Any leaves of intermediate size were removed. Each stem was marked midway between the lowermost young leaf and the uppermost mature leaf, and some of the plants were girdled at this point. At the time of harvesting each plant was separated into: (1) the apex (above the marker on the stem); (2) a 1 cm. portion of stem at the marked region, or in the case of girdled plants, portions of stem both above and below the girdle; (3) the three mature leaves; and (4) the roots. Table 7 gives data from an experiment in which six days were allowed to elapse between girdling and final harvesting. Only the results pertaining to the apex and the stem are given. Table 7 shows that the girdle interfered markedly with the growth of the young leaves, and that the total amount of thiamin above the girdle did not change greatly during the experiment, although the total thiamin content of the corresponding portion of the control plants increased threefold during the same time. The most striking feature of this experiment, however, was the marked accumulation of thiamin below the girdled portion of stem. The concentration of thiamin below the girdle was nearly twice the concentration above the girdle. The concentration of thiamin immediately above the girdle was slightly (but significantly) higher than that in the final control stem. This is probably not to be regarded as an accumulation, however, since the concentration above the girdle is insignificantly different from the concentration in the same portion of stem at the beginning of the experiment.

The accumulation of thiamin below an apical girdle, an observation which has been confirmed in four further experiments similar to that outlined above, suggests that in the plant there may be a movement of thiamin upward in the stem. The fact that thiamin is accumulated above a basal girdle but below an apical girdle further suggests that the mature leaves may export this substance.

EFFECT OF LEAF REMOVAL ON THE DISTRIBUTION OF THIAMIN.—The following experiment was designed to evaluate the relative importance of young and mature leaves in relation to the accumulation of thiamin above a basal girdle. Each of a series of plants was divided into an apex of young leaves and a portion possessing three mature leaves, as described in the preceding experiment. The growing points were then removed from one group of plants and the three mature leaves from a second group. Each group was next girdled at the second node. After six days the plants were harvested, dried, weighed, and assayed for thiamin. Table 8 gives the results pertaining to the regions of stem immediately above and below the girdle in the two groups. In the plants deprived of mature leaves there was no accumulation of thiamin above the girdle. In the plants with mature leaves but deprived of apices there was on the contrary a marked accumulation of thiamin above the girdle. This experiment, which was confirmed by two similar experiments, suggests that the presence of mature leaves is associated with thiamin accumulation in the stem of tomato plants.

Table 9 concerns an experiment similar to that outlined in table 8, except that the plants were not girdled. Removal of the mature leaves checked development of the apex and also diminished the total thiamin increase in the apex during the eight-day experimental period. It should be noted, however, that the apex did increase appreciably in total thiamin, indicating either some capacity for thiamin elaboration in the young leaves or, possibly, transport of thiamin stored in the stem to the growing point. The removal of the apex in the experiment of table 9 was associated with a marked increase in total thiamin content of the mature leaves, a phenomenon which is illustrated more strikingly in the following experiment.

EFFECT OF BUD REMOVAL ON THIAMIN DISTRIBUTION.—The plants used for this experiment were somewhat older than those used previously and were approximately twelve inches tall. All of the plants were decapitated and all but three leaves per plant were removed. One group of plants was allowed to develop new axillary shoots. All lateral buds, as they became evident, were removed from the other group.

After two weeks the plants were harvested, dried, and assayed. The results are given in table 10. Those plants from which buds were removed surpassed the plants upon which lateral buds grew out as to dry weight of the mature leaves, root dry weight, thiamin concentration of mature leaves and roots, and total thiamin content of mature leaves and roots. The accumulation of thiamin in the roots of the disbudded plants is particularly marked. This result, which has been confirmed in a second similar experiment, suggests that shoots and roots may compete for thiamin supplied by the mature leaves.

THIAMIN ACCUMULATION IN GIRDLED PETIOLES.—The following experiment indicates not only that mature leaves of the tomato may export thiamin but also supplies information relative to the vigor with which leaves of different ages carry on this process. Two tomato plants, approximately three feet tall and growing in gravel culture, were trimmed of lateral

shoots. Senescent leaves at the base of the stem were also removed. The remaining leaves were next numbered consecutively starting at the base of the plant and petioles of alternate leaves girdled between the stem and the most proximal leaflets. After seven days, 1 cm. sections were harvested from the petiole of each control (not girdled) leaf and similar sections above and below the girdle were taken from the girdled leaves. Each petiole section was dried,

weighed, and assayed in duplicate for thiamin. The results of this experiment and of a second similar experiment are given in table 11. The younger control (not girdled) petioles had higher thiamin concentrations than the older petioles indicating a concentration gradient in the petioles similar to that obtaining in the entire leaves (table 4). No significant accumulation of thiamin was found on the stem side of any of the girdled petioles. Accumulation of thiamin was

found, however, on the laminar side of the girdled petioles. The accumulation was greatest in the oldest petioles and was smallest in the youngest girdled petiole. Owing to the fact that petioles at least 3 cm. long were needed for the experiment, it was not possible to girdle still younger leaves. In the experiment of table 7, however, the stem was girdled below these younger leaves, and there was no accumulation above the girdle.

The last column of table 11 gives the per cent increase in dry weight of the control (ungirdled leaves) during the seven days of experiment 1. Two leaflets from one side of each leaf were removed at the beginning and the two opposite leaflets were removed at the end of the experiment. The oldest leaves increased in dry weight by 10 to 23 per cent, whereas the youngest leaf increased by 550 per cent. Although the data are slight, still it can be said that accumulation of thiamin in the girdled petioles is in a general way complementary to the growth activity of the leaf in question.

DISCUSSION.—It has been shown that in the vegetative tomato plant there is a thiamin gradient, the highest concentration of this substance being found at the top of the plant in the youngest leaves, with successively lower concentrations in each successively older leaf. A similar gradient was found in the stem. The results of the experiments outlined above

do not suggest, however, that thiamin is transported from young leaves of high thiamin concentration to older leaves and roots having lower thiamin concentrations. Insofar as accumulation above a girdle can be taken to indicate transport in the normal plant, these experiments indicate that thiamin is produced in mature leaves and that this thiamin accumulates in other actively growing parts of the plant. Accumulation of thiamin would appear to be principally in portions of the plant toward which a transport of other materials such as carbohydrate would be expected.

SUMMARY

The distribution of thiamin in the tomato plant was investigated with the aid of an assay based on the thiamin requirement of *Phycomyces Blakeslee-anus*. Data are presented to show that substances interfering with the assay are not present in tomato leaves.

The highest concentration of thiamin in the vegetative plant was found in the youngest leaves. Each successively lower leaf contained a lower concentration of the substance.

Thiamin accumulated markedly above a girdle made by steaming the stems of tomato plants at the second node.

Thiamin accumulated markedly below a girdle made by steaming the stems of tomato plants in the region between the mature leaves and the young rapidly expanding leaves.

The roots of decapitated plants from which all axillary shoots were removed contained more thiamin than the roots of decapitated plants from which axillary shoots were allowed to grow.

Comparative thiamin accumulation in girdled petioles of leaves of different ages indicated that thiamin may be exported by mature leaves having relatively low concentrations of the material rather than by young leaves having higher concentrations of the substance.

STUDIES ON *CHLORELLA VULGARIS*. V. SOME PROPERTIES OF THE GROWTH-INHIBITOR FORMED BY *CHLORELLA* CELLS¹

Robertson Pratt

CELLS OF *Chlorella vulgaris* cultured in a synthetic medium under conditions that are highly favorable for growth produce a substance (or substances) that tends to retard their further multiplication (Pratt, 1940; Pratt and Fong, 1940a). It has been shown that this substance is water-soluble, and that it is capable of passing through the cell membranes, so that it becomes partitioned between the external solution and the *Chlorella* cell contents. The criticisms that have been directed against much of the similar work on protozoa, i.e., that depletion of nutrients, changes in hydrogen-ion concentration, and variable protozoan or bacterial populations in the culture medium influenced the results, have been ruled out of these studies on *Chlorella* (Pratt and Fong, 1940a). Later work by the same investigators has indicated that similar results might be expected whether the nitrogen that is supplied to the cells is combined in nitrate or ammonium ions (1940b).

The work that is reported below was undertaken in an attempt to ascertain some of the properties of the inhibiting agent or agents.

MATERIALS AND METHODS.—The cells were cultured as previously described in a solution that contained KNO_3 , 0.025 M.; KH_2PO_4 , 0.018 M.; $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$, 0.02 M.; $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$, 0.00001 M.; and potassium citrate, 0.00001 M. Microtrophic elements are apparently furnished in sufficient abundance as impurities in the ordinary C. P. grade of salts to satisfy the requirements of *Chlorella* (Pratt, 1941). Therefore, additional amounts were not added in the present experiments as they were in the earlier work. The initial pH value of this nutrient solution was 4.45. A gas mixture that was composed of 5 per cent CO_2 and 95 per cent air was bubbled continuously through the solutions, and the cultures were illuminated continuously from below by water-cooled Mazda lamps that yielded approximately 10,000 lux at the level of the flasks. The temperature varied from 18 to 22°C.

Growth, as indicated by the number of cells in the cultures, was estimated from haemocytometer counts. Cells for inoculating new cultures in the different experiments were always withdrawn from vigorously growing four-day-old suspensions. They were washed by repeated centrifugalization and rinsing in distilled water. The initial population in all experiments was 100 cells per cu. mm., and the initial pH value, except as otherwise noted, was always adjusted to 4.45 ± 0.05 by the addition of KOH or H_2SO_4 . All cultures were shaken twice daily to insure uniform suspension of the cells.

The water used in these experiments was triple distilled, the second and third distillations being carried out entirely in Pyrex glass systems fitted with efficient spray traps. Distillation one was carried out in an ordinary laboratory still. The product that was obtained was treated with KMnO_4 and NaOH and was then distilled in an all Pyrex system. The third distillation, performed without any reagents, was likewise in an all Pyrex system. One set of stills was used exclusively for the second distillation and another set for the third distillation.

EXPERIMENTS AND RESULTS.—I. *Diffusibility of the inhibitor.*—The results of earlier work (Pratt and Fong, 1940a) showed that, as the age of *Chlorella vulgaris* cultures advances, the concentration of growth-inhibitor in the external solution increases, and it was suggested that in old cultures the high concentration in the external solution would tend to retard further outward diffusion of the inhibitor, thus resulting in its accumulation within the cells themselves. Experimental evidence was adduced to support the thesis that cells from old cultures are highly charged with the growth-inhibiting substance, and that, when they are transferred to fresh solutions that lack the inhibiting factor, this substance diffuses out into the surrounding medium.

Therefore, to obtain cells that were highly charged with the growth-inhibitor in the present investigation, cultures were prepared in the usual way and

were permitted to grow for 41 days, at the end of which time they contained approximately 99,000 cells per cu. mm. Most of the cells were removed from 2 liters of solution by centrifugalization and were rinsed twice by suspension in distilled water and recentrifugalization. Then these cells were suspended in 800 ml. of distilled water in a collodion sac that was in turn suspended in 8.5 liters of distilled water which was stirred frequently. The preparation was kept in darkness at 23°C. and periodically 75 ml. portions were withdrawn from the outer solution. The samples that were withdrawn were used to prepare new nutrient solutions with the same concentrations of salts as were used in the standard medium.

The results of two similar experiments performed at different times are shown in figure 1 in which the relative density of population in the different cultures after five days (compared with the population in standard stock cultures of the same age) is plotted on the ordinate, and the length of time the cells were in distilled water before the samples were withdrawn for preparing the nutrient solutions is plotted on the abscissa. Marked exosmosis of various cellular contents in addition to the inhibiting agent would be expected to occur under the conditions of this experiment. Similar subsequent tests with cells from young cultures (two to three days), however, failed to reveal any pronounced effect, either stimulatory or inhibitory, and it seems reasonable to assume, therefore, that the results plotted in figure 1 represent the effects of the *Chlorella* growth-inhibitor that is normally liberated by growing cultures and that they were not brought about by some other cell constituent.

It is apparent that the substance which is produced by *Chlorella* cells and which retards their growth is capable of passing through collodion membranes. The membrane that was employed prevented the passage of eosin and of methyl orange from 0.01 per cent solutions. Somewhat coarser membranes permitted the passage of these dyes. The possibility that electrical or other phenomena prevented passage through the finer membrane has not been definitely eliminated, but it seems safe to conclude tentatively that the molecules of the active substance are smaller than those of eosin which have been calculated to have a diameter of approximately 15 Å units.

The high point that occurs in each of the curves deserves some attention. It might be interpreted to mean that in *Chlorella*, as is true of the response of many organisms to other toxic substances, very low concentrations of the inhibitor are beneficially stimulating; or it might indicate that at least two substances or groups of substances, one stimulatory and the other inhibitory, are liberated by the cells. According to the latter idea, figure 1 would indicate that the accelerating substance is more readily diffusible than the inhibitor, since its influence on the external solution was manifest first, but that it is physiologically less active or is produced less abundantly or is more unstable than the inhibitor.

Although several interpretations of the data that are plotted in figure 1 are conceivable, the simplest one seems to be that the curves reflect in some measure the rate of diffusion of the inhibitor (which may be stimulating in low concentrations), and that they indicate that after 25 to 30 hours an equilibrium was established between the solutions within and without the collodion sac so that there was no further increase in the toxicity of the solutions for *Chlorella*.

Fig. 1. Density of population in cultures of *Chlorella vulgaris* (expressed as percentage of that in control cultures prepared with distilled water) in solutions prepared with water in which *Chlorella* cells in a collodion membrane had been suspended for different periods of time.

II. *Solubility of the inhibitor.*—Cells were removed by centrifugalization from a 21-day-old culture that contained approximately 90,000 cells per cu. mm. and were dried for ten days over H_2SO_4 at a pressure of 3–5 mm. of Hg. Extractions were made in different solvents by placing 500 mg. of dried cells in 50 ml. of the particular solvent for twelve hours, decanting, and then adding 50 ml. of fresh solvent. After a second twelve-hour period the two portions of the solvent were combined and were evaporated to dryness without heat. Distilled water was added to the residue to redissolve the water-soluble fraction, thus eliminating the chlorophyll and much of the extraneous organic matter that was extracted from the cells by the different solvents. Then the preparation was filtered and nutrient solutions were prepared with this water, the volume being adjusted so that the extract from 500 mg. of dried cells was dissolved in 150 ml. of culture medium. These solutions were inoculated and cell counts were made periodically for about one week. The results of this experiment are

presented in figure 2 and table 1. They show that the inhibitor is soluble in the three solvents tested, i.e., 95 per cent ethyl alcohol, petroleum ether, and ether, and they suggest that it may be about twice

Fig. 2. Growth of *Chlorella vulgaris* in solutions containing material extracted in ether (circles with solid uppers), petroleum ether (solid circles), and 95 per cent ethyl alcohol (circles with solid lowers). The open circles represent growth in control cultures prepared with distilled water.

as soluble in the first of these as in either of the other two. The possibility should not be overlooked, however, that some other extraction technique would yield somewhat different values. It has been shown that the amount of growth hormone that is extractable from maize endosperms depends in large measure upon the extent of hydration of the tissue (Avery, Creighton, and Shalucha, 1940), and that in several types of plant tissues water is essential for

the extraction of auxin (Thimann and Skoog, 1940). Although the growth-retarding factor in *Chlorella* seems to differ in some respects from the recognized auxins, it is conceivable that some of the problems involved in its extraction may be similar to those encountered in plant hormone studies.

III. *Heat stability of the inhibitor.*—Cultures were prepared as in previous experiments and were permitted to grow for thirty days at the end of which time the mean density of population of the different cultures was 101,500 cells per cu. mm.

Two liters of the suspension were completely freed of cells by centrifugalization and subsequent passage of the supernatant liquid through Jena-glass filter sticks, No. 17G. The pH of the resultant filtrate was 6.55. These two liters were divided into ten portions of 200 ml. each. One portion was used immediately and without further treatment for the preparation of a new culture solution, the pH of which was adjusted to 4.5.

Each of the other portions was placed over a hot flame and rapidly brought to the boiling point, after which gentle boiling was maintained for different lengths of time. New culture media with pH values of 4.45 ± 0.05 were prepared from each of the different solutions after they were cool, and the original volume was restored by the addition of distilled water. All solutions were then inoculated and the density of population in the different cultures was determined after seven days.

The results that were obtained are plotted in figure 3 (open circles) where the density of population in the different cultures relative to that in the normal control solution is plotted on the ordinate, and the length of time the different solutions were boiled is shown on the abscissa. This experiment demonstrated clearly that the inhibitor is destroyed by boiling, and that the destruction is approximately a linear function of the length of the exposure to boiling. It did not show, however, whether or not oxidation

TABLE 1.

Relative growth of <i>Chlorella vulgaris</i> in solutions containing material extracted from <i>Chlorella</i> cells in:				
Time, hours	95% ethyl alcohol	Petroleum ether	Ether	Control: no extract
0	100 ^a	100 ^a	100 ^a	100
37	43.6 ^b	58.7 ^b	56.7 ^b	100
67	55.4	79.0	83.0	100
95	50.7	80.6	60.5	100
113	49.9	80.0	85.2	100
161	58.8	80.4	87.5	100
Averages	51.7	75.7	74.6	
	53.7*	80.0*	79.1*	

^a These figures are not included in the averages.

^b These figures are omitted from the averages marked with asterisks. It is apparent that these figures are considerably lower than the general trend in the respective series. It is not clear at present whether or not their omission can be justified on the grounds that an adaptation period was required for adjustment to the new environment in the different cultures and that the first observations are not as reliable as the later ones. Therefore, averages calculated both ways are given.

played a part in the destruction. It was repeated, therefore, with a modified technique that would tend to prevent oxidation or at least reduce it to a minimum.

Nitrogen that had been passed over hot copper and that had been cooled subsequently by passing through coils submerged in ice water was bubbled through the solutions for twelve hours before they were heated and also while they were boiling. The results are plotted in figure 3 (solid circles). Although the relative populations in the cultures of this experiment differed appreciably from those in the previous one, the general character of the results is similar. After the initial periods, in the results for which some deviation might be expected, since a short period of time was required to elevate the temperature of the solutions to the boiling point, both curves are approximately linear and both have nearly the same slope. The fact that the growth that is represented by the second curve (solid circles) was consistently 10 to 15 per cent less than that in the first experiment (indicating higher concentrations of inhibitor in the solutions) may mean that the destruction of the inhibitor in the first experiment was due in part to oxidation. However, it seems clear that an oxida-

Fig. 3. Density of population in cultures of *Chlorella vulgaris* (expressed as percentage of that in control cultures prepared with distilled water) in solutions prepared with *Chlorella* filtrate that was boiled for different periods of time. Open and solid circles represent different experiments. See text for explanation.

tive mechanism could have accounted for only a small part of the inactivation, and that destruction was probably accomplished principally by hydrolysis or pyrolysis, or perhaps by both.

In another experiment 500 mg. of dried *Chlorella* cells were heated at 100°C. for two hours in a continuous stream of nitrogen that had been passed over hot copper and that had then been cooled. These cells were extracted with 95 per cent ethyl alcohol as described above. The extract was evaporated to dryness and the water-soluble fraction was taken up in distilled water as outlined earlier. This extract was found to be incapable of significantly inhibiting the

growth of *Chlorella*. Although this experiment does not eliminate hydrolysis as a possible mechanism for effecting destruction of the *Chlorella* inhibitor, it does demonstrate that such destruction may be brought about by heat alone.

Fig. 4. Growth of *Chlorella vulgaris* in solutions containing material extracted by ether from aqueous *Chlorella* filtrate at pH 4.1 (circles with solid uppers), and pH 8.8 (solid circles). The open circles represent growth in control cultures prepared with distilled water.

IV. *Extraction of the inhibitor from acid and alkaline solutions.*—Cells were removed from a 28-day-old culture by the usual centrifugalization and filtration. The pH of the resulting filtrate was 6.3. Two 200 ml. portions were withdrawn, one of which was acidified to pH 4.1 and the other alkalized to pH 8.8 by the addition of H_2SO_4 and KOH , respectively. Each portion was extracted with dry ether for eighteen hours, after which time the ether extracts were removed and were evaporated to dryness without heat. Each extract was suspended in 200 ml. of distilled water which was stirred for two to three hours. Then the samples were filtered, and the filtrate was employed in the preparation of new cultures. Cell counts were made periodically during approximately one week.

The data from this experiment are shown in figure 4 and table 2. The curves show the actual cell counts in each of the cultures at different times, and the tabularized data show the growth in the two experimental cultures relative to that in the control culture prepared in the usual way with distilled water.

Clearly, the inhibitor is more easily taken up in ether from an alkaline aqueous solution than from one with an acid reaction. This may be interpreted to mean that the inhibiting substance is an organic base which is converted into a salt in an acid medium. Sufficient quantities of the compound to permit chemical analysis have not yet been separated.

TABLE 2.

Time, hours	Relative growth of <i>Chlorella vulgaris</i> in solutions containing material extracted by ether from aqueous <i>Chlorella</i> filtrate adjusted to:		
	pH 4.1	pH 8.8	Control: no extract
0	100 ^a	100 ^a	100
22	61.5 ^b	11.2 ^b	100
48	82.2	17.5 ^b	100
93	87.8	74.0	100
115	86.1	60.5	100
161.5	78.3	69.3	100
Averages	79.2	46.5	
	83.6*	67.9*	

^a These figures are not included in the averages.

^b These figures are omitted from the averages marked with asterisks. It is apparent that these figures are considerably lower than the general trend in the respective series. It is not clear at present whether or not their omission can be justified on the grounds that an adaptation period was required for adjustment to the new environment in the different cultures and that the first observations are not as reliable as the later ones. Therefore, averages calculated both ways are given.

V. Activity of the inhibitor in acid and basic media.

—Accepting the assumption that the *Chlorella* inhibitor is a basic compound, it seemed of interest to determine whether its retarding action on growth is greater in the basic form, which might or might not be dissociated, or in the salt form, which would be expected to be at least partially dissociated in aqueous solutions. One observation that may bear on this point is the fact that the growth of *Chlorella* in solutions with the salt composition used in these experiments is less vigorous in media with initial pH values of about 6.0 than in those with initial values of about 5.20 or less (Pratt and Fong, 1940b).

The problem is complicated, however, because, under the conditions of the experiments, the hydrogen-ion concentration changes continuously (Pratt and Fong, 1940b). Furthermore, as might be expected, and as these workers showed, the hydrogen-ion concentration of the medium is so intimately related to other factors concerned in the growth of *Chlorella* that changes in the pH value immediately bring about a readjustment among numerous other component forces that influence the rate and amount of growth.

Nonetheless, several culture solutions were prepared with the cell-free filtrates obtained from 32-day-old cultures, the average population of which was 98,300 cells per cu. mm. The initial hydrogen-ion concentrations were adjusted to different levels so that the pH values ranged from 3.5 to 7.2. No precipitation was evident in any of the cultures even at the higher pH values. All media were clear at the time of inoculation.

The data that were obtained are presented in figure 5 where ordinates represent the relative density of population in the different cultures after seven

days (compared with the population in the control cultures prepared with distilled water) and the abscissas show the initial pH values of the different solutions. The solid and open circles represent data from two separate experiments that were performed at different times.

Although the quantitative agreement of the data from the two experiments is poor and even the apparent shapes of the curves seem to be somewhat different, one significant feature is evident in both curves, viz., the left extremity is markedly higher than the right. As the initial hydrogen-ion concentration decreased (increase in pH) the amount of growth, relative to the control, also decreased.² The inhibitor was more effective in checking growth at relatively high pH values than at lower ones.

Fig. 5. Density of population in cultures of *Chlorella vulgaris* (expressed as percentage of that in control cultures prepared with distilled water) in solutions prepared with *Chlorella* filtrate and adjusted to different initial hydrogen-ion concentrations. Open and solid circles represent two different experiments.

As was pointed out before, this type of experiment is beset by many complications, and it would be dangerous to make a categorical interpretation of the results. The data presented in figure 5 do not prove that the inhibitor is more effective in the basic form, but since the value of the ratio base/salt should increase with the pH, they may be considered as preliminary circumstantial evidence that this is so.

VI. Do *Chlorella* cells produce a substance that is different from the inhibitor and that accelerates their growth?—It was pointed out above that the curves in figure 1 might indicate the presence of two substances, one that accelerates growth and another that inhibits growth, in the diffusate from the *Chlorella* suspension. This is a point on which it is difficult to give a definite answer at present. Positive results from experiments might prove the existence of two

² Growth was poor in all solutions, including the controls, with pH values of 6.0 or higher, but since the results are all relative, valid comparisons may be made.

substances but negative results would not necessarily disprove their existence. Several experiments were performed in an attempt to solve the problem.

It seemed that if a specific accelerator were formed, and if it diffused through collodion membranes into distilled water more readily than the inhibitor, one might expect the solution retained by the membrane to contain a relatively higher effective concentration of inhibitor after a short time than a similar solution that had not been so separated from distilled water. The net inhibiting action of such a solution should be greater, since some of the accelerator that would tend to nullify the effect of the inhibitor would have been removed.

Accordingly, such an experiment was prepared. Cells were treated as described in section I, and one portion of the dense cell suspension was placed in a collodion bag that was suspended in distilled water, while another portion was retained for a control. After three hours and again after six hours, cells were removed from 200 ml. portions of the suspension within the collodion sac and from the original suspension that had not been dialyzed. Fresh culture media were prepared from the cell-free solutions and they were inoculated with new cells. The experiment was repeated three times but in no case were significant differences in the growth in the different cultures detected.

It seemed possible that if two substances that exerted opposite actions were present, they might differ in some of their properties, such as solubility, heat lability or stability, etc.

Accordingly, cell-free samples removed from within the collodion sac after three and six hours, respectively, were compared with similar cell-free samples removed from the control suspension.

In one set of experiments the filtrates were heated following treatment with nitrogen, as described in section III and their effect on the growth of *Chlorella* was tested. No significant differences were detected, indicating that if two substances of opposing action are formed by *Chlorella* cells, both are destroyed by heat at the same rate.

Similar negative results were obtained from experiments that were designed to test the relative solubilities of the two substances, if such existed, in ether, petroleum ether, and 95 per cent ethyl alcohol.

DISCUSSION.—The object of the experiments that are reported in this paper was to ascertain some of the properties of the growth-retarding substance that is formed by *Chlorella* cells. A discussion of the literature that deals with the evidence for and against the production of auto-inhibitive and auto-stimulative substances by microorganisms would, therefore, be out of place. It does seem worth while, however, to point out that, despite the vast literature on the subject, there are relatively few clear cut cases in which the production of auto-inhibitive substances has been conclusively demonstrated. Virtual proof of the existence of such compounds among micro-organisms

has been published by Mast and Pace (1938; protozoa), Pratt (1940; *Chlorella*), Pratt and Fong (1940a; *Chlorella*), and Kidder (1941; protozoa). Similar observations have been recorded for echinoderms (Springer, 1922; Peebles, 1929).

None of the attempts to determine the nature of the retarding agents from the different organisms has been particularly fruitful, principally because the compounds are formed in such minute quantities that attempts to isolate appreciable amounts of them have been uniformly unsuccessful. It seems possible that these naturally-formed growth-inhibiting agents may prove to be among the most potent of biologically-produced chemicals. Mast and Pace (1938) estimated that the substance formed by *Chilomonas paramecium* exerted a measurable effect when present in the culture solution in a concentration of 1 part in 800,000,000.

The inhibitor formed by *Chlorella* cells resembles that found in the protozoa, *Chilomonas paramecium* (Mast and Pace, 1938), and *Tetrahymena geleii* (Kidder, 1941) in that it is destroyed by heat.

Peebles (1929) and Kidder (1941) have published evidence that seems to indicate that during the course of development growth-accelerating substances may be produced along with growth-inhibiting agents. It was pointed out that some of the data in the present report could be interpreted as indicating the presence of a growth-accelerator in the *Chlorella* cultures. Subsequent experiments that were designed specifically to elucidate this question failed to yield positive experimental evidence to support such an idea, however, and the simpler hypothesis for the present seems to be that the increased growth that was observed under some conditions was merely the result of stimulation from exposure to exceedingly low concentrations of a "poison."

SUMMARY

The experiments that are reported in the present paper constitute a continuation of previous studies on the growth of the uni-cellular green alga, *Chlorella vulgaris*, in which it was shown that during the course of their development *Chlorella* cells produce a growth-inhibiting substance. Experiments that were designed to reveal some of the properties of the growth-retarding agent are described.

It was found that the inhibitor diffuses through collodion membranes, and that its molecules are probably less than 15 Å units in diameter.

The inhibitor is soluble in 95 per cent ethyl alcohol, ether and petroleum ether, being about twice as soluble in the first of these solvents as in either of the other two.

It is destroyed by heat. Relatively little, if any, of the destruction is caused by oxidation.

The inhibitor is more readily extracted by ether from an alkaline aqueous solution than from one with an acid reaction. From this it is concluded that the active agent is probably an organic base.

Chlorella filtrate that was highly charged with growth-inhibitor checked growth more effectively at relatively high pH values (6.5 to 7.0) than at relatively low values (3.5 to 4.0). This indicates that it is more effective in the basic form than in the salt form that might be expected to exist in the more acid media.

Exceedingly low concentrations of the inhibitor seem to exert a beneficially stimulating effect on *Chlorella* cells.

SOME RESPONSES OF VALENCIA ORANGE SEEDLINGS TO VARYING CONCENTRATIONS OF CHLORIDE AND HYDROGEN IONS¹

H. E. Hayward and Winifred M. Blair

MUCH of the citrus produced in the western and southwestern states is grown under conditions involving some degree of salinity of the soil solution. It has seemed desirable to extend the investigations noted below to include the anatomical and physiological responses of citrus seedlings to controlled concentrations of chloride and hydrogen ions. Since the root is in most intimate contact with the soil solution, emphasis has been placed on the structural and functional behavior of that organ in relation to the conditions imposed upon the experimental plants.

The nutritional requirements of citrus seedlings have been investigated with respect to nitrogen and the absorption of other essential ions (Breazeale, 1919; Chapman and Liebig, 1937, 1940); and the response of seedlings grown in water cultures to various environmental factors—temperature, aeration, and hydrogen ion concentration—has been studied (Girton, 1927). The absorption of chloride by rough lemon and *Poncirus trifoliata* seedlings in relation to the intake of nitrate, calcium, and sodium ions has been investigated by Haas and Reed (1926), and the same authors have reported on the effects of sodium, potassium and calcium on young orange trees (1923). The anatomy of citrus roots has been examined in relation to osmotic pressure and periodicity

of growth (Cossmann, 1939), and the developmental anatomy of the seedling and roots of the Valencia orange has been described by Hayward and Long (in press).

METHODS AND EXPERIMENTAL DESIGN.—The seedlings were grown in water culture to permit periodic observation of the developing roots and to determine their condition with respect to lateral root formation, production of root hairs and other growth responses. Since it has been noted (Hoagland and Arnon, 1938) that aeration of the culture solution may have a marked effect on the development of the plant, half of the cultures under each treatment were aerated by a low pressure continuous flow system while the other half were maintained without aeration.

Selected Valencia orange seeds were germinated in *Sphagnum* moss in September, 1940, and in November 288 of the most uniform were divided into thirty-six groups of eight each. Each lot was assigned by chance to one of the designated cultures which were randomized on greenhouse benches.

Three culture solutions were used: (1) the base nutrient solution, Hoagland's number two (1938),² (2) the base nutrient solution plus 50 m.e. chloride per liter, (3) the base nutrient solution plus 100 m.e.

² This solution contains the following salts:

chloride per liter. The chloride for solutions 2 and 3 was supplied as NaCl 50 per cent, MgCl₂ 25 per cent and CaCl₂ 25 per cent. Micro-elements were added in the following concentrations: boron, 0.5 ppm.; manganese, 0.5 ppm.; zinc 0.05 ppm.; copper 0.02 ppm.; molybdenum, 0.01 ppm. Five ppm. of iron was added initially as citrate, and further additions were made as needed.

Two levels of hydrogen ion concentration were maintained by daily adjustment of the pH values

with HNO₃ or KOH: Series A—pH value within range 5.5 to 6.0; Series B—pH value within range 7.5 to 8.0. Half of the cultures in each series (designated with an O) were aerated with a carbon pipe aerator operated under a continuous pressure of approximately 8 pounds. The other half (without the O designation) were unaerated. Each treatment was replicated three times.

All the seedlings were started in the base nutrient solution, and the pH value was adjusted within the

Fig. 1. Valencia orange seedlings at the conclusion of the experimental period showing relative development under the various treatments. Each panel represents the seedlings in one replication. The A and AO series were maintained at pH 5.5-6.0, the B and BO series at pH 7.5-8.0. The cultures designated with an O were aerated. No. 1 cultures contained the base nutrient solution, No. 2 the base nutrient solution with 50 m.e. chloride per liter added, No. 3 with 100 m.e. chloride per liter added. The smaller number of plants in the No. 3 cultures represents the approximate mortality incurred under that treatment.

specified range of the series. In treatments 2 and 3, the chloride salts were added by increments of 25 milliequivalents per liter at two-day intervals until full concentration was reached, and complete changes of all solutions were made as required. The plants were grown for about two months, the final harvest being January 28, 1941.

GROSS MORPHOLOGICAL AND PHYSIOLOGICAL RESPONSES.—Differences in leaf color were detectable between the A and B Series within a week after the solutions were up to full concentration; and, at the end of two weeks, the leaves of plants grown at the lower pH value were definitely darker green. Chlorosis was more pronounced at the high chloride levels in all series, but was intensified by high pH values (table 1). Under equivalent salt treatments, the plants in aerated cultures were somewhat more chlorotic.

Chloride injury was indicated by tip burn of the leaves. This symptom was noted first in the high chloride cultures two weeks after the solutions were brought to full concentration. The degree of burning was conditioned by the hydrogen ion concentration of the solution and by aeration at the highest chloride level. Burning was most severe in the aerated cultures of the 100 m.e. chloride solution maintained at pH 7.5-8.0 and least in base nutrient solutions regardless of aeration (table 1). The tip burn was progressive and tended to involve more and more of the blade until the entire leaf became brown and desiccated. This was most pronounced in the high salt-high pH cultures.

Growth was inhibited at the high chloride levels, and this was intensified by low hydrogen ion concentration. There were fewer, smaller leaves and fewer, shorter, lateral roots on plants grown under these conditions (fig. 1). A highly significant reduction

in the total length of plants, total fresh and dry weights, number of lateral roots and white root tips occurred under the high chloride treatments. The effect of the higher pH value was also highly significant; in fact, the response to this factor was greater than to increased chloride treatment. On the basis of all treatments, no significance could be determined for aeration, although, at the lower pH value, aeration did influence the dry weight of seedlings significantly. The failure to get significant differences between aerated and non-aerated cultures might have been due to the presence of enough oxygen in the non-aerated solutions to meet the requirements of the slowly growing roots. The harvest data are shown in table 2.

ROOT DEVELOPMENT.—The response of a plant to varying conditions of the soil or nutrient solution is intimately associated with the anatomy and physiology of its roots. Numerous investigators have observed that the extent of the absorbing zone of a root will vary with changes in external conditions, such as soil moisture, temperature, and aeration. Scott (1928) refers to the effect of temperature on the water roots of *Salix*, and Plaut (1910, 1919) reports the closure of the absorbing zone during conditions unsuitable for growth in forest trees. The development of a protective suberized layer, the metacutis, which closes the absorbing zone has been described for a number of plants by Kroemer (1903-4), Plaut (1919), and Müller (1906). Cossmann (1939) has pointed out that suberization in the root of citrus belongs to a simple type where a metacutis to two to three rows of cells is formed in the root cap adjacent to the growing point.

The roots of citrus grow slowly and may exhibit alternating phases of activity and dormancy (Reed and MacDougal, 1937). During the active period,

Fig. 2-5.—Fig. 2. Median longitudinal section of an active root tip showing meristematic region and root cap.—Fig. 3. The same, showing the initiation of the metacutis, indicated by the zone of deeply stained cells extending through the root cap.—Fig. 4 and 5. Later stages in growth inhibition showing roots in the dormant state with heavily cutinized epidermis and metacutis and reduced root cap.

6

7

8

9

the cells of the terminal meristem divide, adding new cells to the root cap distally and to the epidermis, cortex, and stele proximally (Hayward and Long, in press). The root cap is acute to sub-acute, and the outermost cells have thick heavily suberized or lignified walls. As the root elongates the peripheral cells of the root cap are lost, and the underlying ones form the suberized protective layer (fig. 2).

Under the influence of environmental factors which induce dormancy, the cells of the epidermis adjacent to the root cap become filled with deeply staining substances, and a similar condition develops in the cells of the hypodermis. There is a progressive extension of this reaction that involves one or two layers of root cap cells in a zone lying two or three cell layers outside the meristematic region (fig. 3). The cells of the deeply-stained layers become thick-walled, and there is a deposition of suberin on their inner faces. As a result, the cells of the distal portion of the root cap outside the suberized layer die (fig. 4). Coincident with these changes in the cells of the protective tissues, the activity of the meristematic cells diminishes. Continued differentiation results in mature stelar elements adjacent to the much reduced meristematic region (fig. 5).

The root tips in the resting stage are brown with flattened root caps in contrast to the actively growing root tips that are white with conical caps (fig. 2, 5). Senescent root tips resemble those of resting roots and may become gelatinized as necrosis progresses.

The resumption of active growth by a dormant root is initiated in the meristematic cells of the growing point and the cells of the pericycle adjacent to it (fig. 7). The combined activity of these cells produces a broadened growing point which forms new root cap cells inside the metacutis. As growth proceeds, the old root cap and metacutis are ruptured and displaced laterally, forming a shoulder of dead and broken cells which marks the point of renewed activity (fig. 8). There is no break in the continuity of the stelar elements, and the new ones are differentiated against the older ones, but at the point of resumption of activity the newly formed epidermis can be distinguished from the older epidermal cells by the degree of suberization and the presence of root hairs (fig. 9). The activation of the pericycle cells forces the endodermal layer toward the periphery of the root, and a separating zone is formed between the cortical parenchyma of the old and new growth. Cossmann (1939) describes a somewhat similar development as the formation of "a direct link of suberized cells . . . formed between endodermis and exodermis."

ANATOMICAL RESPONSES TO TREATMENTS.—Although brown roots, indicative of the dormant phase that commonly occurs in the ontogeny of the citrus

seedling, may resume active growth and form new white tips under normal circumstances, they will not do so if sufficiently high salt concentration and high pH values are maintained. In such cases, the inhibiting effects of high concentrations of chloride salts and low hydrogen ion concentration were reflected in an increased number of brown roots and a reduction in white root tips (table 2). In some instances, no white root tips were found on seedlings grown at the highest chloride level. In the most severe treatments, the brown inhibited condition was frequently followed by a breakdown of the meristematic tissue of the root and death of the seedling.

The histological picture accompanying progressive inhibition involves: (1) the reduction of meristematic activity in both the growing point and the pericycle zone, (2) the continued maturation of the stelar tissues until they abut the meristematic zone, and (3) a marked increase in the deposition of suberin on the walls of the epidermal, hypodermal, and root cap cells.

The inhibition of meristematic activity results in the formation of fewer cells by the histogens and a slower growth rate in the cells produced. In the pericycle, the potential cortical cells may not enlarge to the size they attain in the base nutrient solution, and in consequence the root may be smaller in diameter than those of the control plants. The stelar tissues continue to differentiate, and mature xylem and phloem elements ultimately abut the reduced meristematic zone thus eliminating the regions of elongation and differentiation that usually occur between the meristem and the mature primary tissues of the stele. This means that the processes of cell differentiation and maturation have proceeded at a relatively more rapid rate than that of cell division.

Another effect of high chloride and low hydrogen ion concentration is the reduction of pericycle activity in the formation of lateral roots. Except in the B series (unaerated, high pH value), there was a highly significant reduction in the number of lateral roots formed at the high chloride levels (fig. 1) (table 2).

Suberization of the walls of epidermal and hypodermal cells which normally accompanies dormancy was accentuated under high chloride conditions, and this was more pronounced in cultures where high chloride concentrations and high pH values were combined. The retardation in meristematic activity and consequent reduction in the production of new root cap cells, plus the development of a heavily suberized metacutis, results in a blunt root cap with few peripheral cells. One or two layers of cells may remain between the metacutis and the dermatogencalyptrogen layer (fig. 5).

THE DEVELOPMENT OF ROOT HAIRS.—The effect of hydrogen ion concentration, temperature and aera-

tion on root hair formation has been noted by Girton (1927). Under the conditions of his experiments, he found the most favorable conditions at pH 5.0 and 33°C. and demonstrated that continuous aeration greatly enhanced production. Cossmann (1939) observed that the length and development of root hairs was "directly affected by soil moisture conditions."

With respect to hydrogen ion concentration, our results confirm those of Girton. Seedlings growing in solutions maintained at the lower pH values (5.5-6.0) produced more root hairs than those growing in solutions having equivalent amounts of chloride salts but with pH values ranging from 7.5 to 8.0. Although low hydrogen ion concentration was the most important factor in inhibiting root hair formation, high concentration of the chloride ion was also a vital one. With one exception (the 100 m.e. chloride culture in the B series), there was a significant reduction in the number of root hairs at the high chloride levels. No root hairs occurred on plants in the aerated cultures at the high pH level in the 50 and 100 m.e. chloride solutions. In the base nutrient cultures, more root hairs were produced by the aerated than the unaerated plants as noted by Girton, but at both levels of hydrogen ion concentration, the high chloride

seedlings in the aerated cultures produced fewer root hairs than those in the unaerated solutions (table 3).

The treatment also influenced the length of root hairs. In general, the root hairs formed by this variety of orange are tubular, although some papillate, spatulate, and irregular forms do occur. In no instance were long root hairs developed, and under the most favorable conditions they seldom exceeded 100 μ in length. High hydrogen ion concentration favored development of the longest root hairs, but they were observed only in the control cultures of the A and AO series. The depressant effect of chloride was indicated by the shorter root hairs found in the 50 m.e. chloride cultures in both the A and AO series, and at the 100 m.e. level of the A cultures. At the high pH values, the development of root hairs was limited to the formation of primordia confirming Girton's results with respect to the effect of low hydrogen ion concentration.

The persistence of root hairs of the Valencia orange has been noted in a previous report (Hayward and Long, in press). The root hairs may become suberized and lignified, and in such cases persist for some time, although it seems unlikely that they remain functional. We have noted cases where

TABLE 4. *Mortality data.*

	3—1-00 m.e. Cl ⁻ /l.	13	54	48

root hairs have remained intact until the underlying hypodermal layer has divided periclinally to initiate a phellogen. The development of such hairs was more common with low hydrogen ion concentration than with high as might be expected on the basis of the relative degree of suberization of epidermal and hypodermal cells occurring under such conditions.

MORTALITY.—During the course of the experiment, 51 plants, or 17.7 per cent of the total population, died. Except for three seedlings in the A series that died at the end of two weeks while apparently in good condition, death was preceded by a slow progressive chlorosis and burning of the leaves accompanied by a gradual browning of the lateral roots. The color of the root tips changed from a glistening white to dull brown, and frequently this was accompanied by a gelatinization of the tissues of the root tip so that they appeared semi-translucent.

The major portion of the fatalities occurred between 35 and 50 days after the seedlings had received full treatment. No deaths occurred in the base nutrient cultures in either series and few at the 50 m.e. chloride level. At the 100 m.e. level, over 50 per cent of the population died in each of the AO, B, and BO treatments. The effect of high chloride was intensified by low hydrogen ion concentration. With high hydrogen ion concentration, the mortality rate at the high chloride level was significantly lower in the unaerated cultures (table 4).

SUMMARY

Valencia orange seedlings were grown in water cultures under three salt treatments: (1) a four-salt base nutrient solution containing no chloride except for a small amount occurring in the tap water (0.35 to 0.55 m.e./l.), (2) the nutrient solution plus 50

m.e. chloride per liter, and (3) the nutrient solution plus 100 m.e. chloride per liter. Chloride was supplied as NaCl 50 per cent, $MgCl_2$ 25 per cent, and $CaCl_2$ 25 per cent. Solutions were adjusted to pH 5.5–6.0 in one series and to pH 7.5–8.0 in the other. Half of the cultures of each series were aerated.

Citrus roots may exhibit alternating phases of activity and dormancy in their usual growth cycle. When in the dormant condition, meristematic activity is diminished and the walls of the cells of the epidermis and root cap adjacent to the meristem become suberized, forming a metacutis.

The anatomical response of the root to high chloride concentrations and high pH values resembles that of dormancy, but may be accentuated. In extreme cases, the root may remain in the dormant condition until death ensues.

Few root hairs developed on roots grown under conditions of low hydrogen ion concentration, and these were usually short or primordial in character.

The frequency and length of root hairs was reduced by high concentrations of chloride salts.

Chlorosis and tip burn of leaves may be induced by high chloride or low hydrogen ion concentration; the most severe symptoms occurred when the two treatments were combined.

Growth was inhibited under high chloride treatment and high pH values, fewer leaves and lateral roots being produced. The plants were shorter and lighter under such conditions.

Mortality was highest at the 100 m.e. chloride level in all series; few plants died under the 50 m.e. chloride treatment and none in the control cultures.

PASSAGE OF AIR THROUGH PLANTS AND ITS RELATION TO MEASUREMENT OF RESPIRATION AND ASSIMILATION¹

Violette F. C-Glasstone

DURING THE course of preliminary respiration experiments with entire plants, it was found that air passes readily through the tissues either upward or downward. Since this finding was of some importance in connection with work on respiration, the results obtained were thought to be of sufficient general interest to justify a report. Plants in earthenware porous pots filled with soil, the surface of which was covered with a low-melting-point hydrocarbon wax mixture, were used. Particular care was taken to see that the soil was completely covered and that a good seal was made around the stem. While the wax was still fluid, a glass respiration chamber was placed over the shoot, which was thus completely enclosed; the system was apparently airtight as soon as the wax set hard. Air from a compressed air main was first freed from carbon dioxide and then passed into the respiration chamber; it left via an exit tube which led to a carbon dioxide absorption tower and thence to a vacuum tap. The only other opening to the respiration chamber was for a manometer, to indicate the pressure; by manipulating the compressed air and the vacuum valves, a steady rate of flow at atmospheric pressure was maintained. In testing the apparatus for leaks, a porous pot containing soil but no plant was poured with wax as described and the chamber sealed into place. The apparatus proved to be perfectly airtight; and, in fact, the manometers were so very sensitive that special precautions had to be taken to minimize the inevitable changes in vacuum or air pressure.

When experiments were made with pots containing plants, negligible and zero amounts of carbon dioxide were taken up in the absorption towers; this result suggested that no respiration was taking place, a conclusion which was obviously incorrect. It was noticed, however, that the manometers attached to the chambers containing the plants had ceased to show the sensitive movements, since use of either vacuum or compression line produced only slight positive or negative pressures. Similar results were obtained by using plants from which the shoots had been excised, leaving only cut stumps protruding through the wax. These facts suggested that air was passing right through the plants.

Confirmation of the fact that air was able to pass readily through plants was obtained by replacing the porous pot with a non-porous glass container. After a few minutes, equilibrium was attained and the manometers became exceedingly sensitive. Under these

conditions, normal respiration measurements could be made.

EXPERIMENTAL METHOD.—Experiments on the rate of passage of air through plants were carried out in the following manner. The specimen was placed in a porous pot with a respiration chamber sealed over the shoot as usual. A manometer containing *n*-butyl phthalate was fixed in position, and the only other opening was occupied by an exit tube leading first to a flow meter, next to a 20-liter glass jar which acted as a storage tank, and then to a T-tube connecting either to the vacuum tap or compressed air tap as desired. The vacuum tap was turned on until the manometer liquid just began to move; after a time the levels were noted and the suction increased. This procedure was continued until the maximum rate of flow measurable on the flow meter was reached. Analogous experiments were carried out using compressed air, instead of vacuum, and thereby reversing the direction of air flow. The levels in the manometer and flow meter at any rate of flow could be held stationary and the flow of air continued apparently indefinitely.

RESULTS.—Table 1 shows a typical set of readings obtained with a plant of *Nicotiana sylvestris* Speg. and Comes, of which the fresh shoot weighed 28.5 gm. and the area of under surface of leaves was about 878 sq. cm.

It will be observed from the figures in the last column that there was an approximate proportionality between the rates of air flow and the difference of pressure between the experimental chamber and the external atmosphere as measured by the manometer. The proportionality constant expressed in liters of air passing through the plant per hour per cm. of *n*-butyl phthalate is called the "rate coefficient" throughout this paper.

Similar results were obtained with all the plants tested: the data are summarized in table 2. The observations for each plant were reproducible over many hours; and where, as will be noted later, certain changes took place in the rate coefficient, these effects were also reproducible.

In some plants the rate coefficients were the same for either direction of flow, while in others there were differences in the two directions, *i.e.*, from leaf to root and root to leaf, respectively. Wherever two rate coefficients are given in column 4, as for example Oriental Poppy 5.5–35.0 liters per hour per cm. *n*-butyl phthalate, the air passed through the plant at the highest value for low rates of flow. When attempts were made to exceed a certain rate of flow, varying with each species, a resistance developed which diminished the rate coefficient until a certain pressure was attained. After a time at this high pressure, a new steady state was established, and the air

¹ Received for publication September 29, 1941.

This work was carried out in the Plant Pathology Division of The Rockefeller Institute for Medical Research at Princeton, New Jersey, and thanks are due to the Directors for their kindness in granting permission to use the laboratory facilities. The author wishes to thank Dr. L. O. Kunkel for his continued interest and encouragement.

	58.5	4.4	13.3

^a One cm. of butyl phthalate is equivalent to about 10^{-3} atm. pressure.

usually passed through the plant at the higher speed. In most of the plants which showed this effect, the change, at the high pressure, from slow to high speed was very sudden. The pressure at which the rapid change occurred was fairly constant for each species and could be repeated apparently indefinitely by allowing a period of time to elapse or by reversing the air current. For the purpose of determining

whether the presence or absence of water within the plant or soil was a possible factor, a zinnia plant was well watered before being used. The experiment was continued on the same plant for two days. No water was added during the period but, since it was left sealed in the chamber all the time, the gradual loss of water was not serious, and the plant remained in good condition to the end of the test. Quite early on

^a The explanation for the two rates is given in the text.

the first day the rate coefficient for passage of air from root to leaf suddenly increased to the high value of 30 l./hr./cm. pressure; while the low value of 9 l./hr./cm. pressure continued for the passage of air in the opposite direction. It was demonstrated repeatedly that reversal of air flow, or the passage of time, allowed a resumption of the resistance to the flow of air from root to leaf, and that the sudden change in rate coefficient always occurred at the same pressures. It was not until the latter half of the second day, in the case of the flow in the direction from leaf to root, that the rate coefficient began to increase gradually until it approached that of the flow in the opposite direction, i.e., 30 l./hr./cm. pressure.

In the case of *Nicotiana sylvestris* the leaves grow in a rosette, and the wax was poured so as to flow into the heart of the rosette and to cover all the leaf bases: no stem was above the surface of the wax. It was, therefore, certain that the air must have passed through the leaves. Other experiments were devised to expose either stem, root, or leaf only above the wax surface.

Plants of sunflower, tomato, *Datura* and tobacco were grown until the leaves from the lower part of the stem had died back naturally; the upper portion of the stem with leaves was cut off and the cut surface sealed with wax. These plants were used with the stump varying from 18–25 cm. long protruding above the wax. The rates of passage of air showed a proportionality as before, but the rate coefficients were considerably lower at 1 to 2 l./hr./cm. The stems were not able to allow a flow of air above an average of 10 l./hr. The tobacco stem, however, was exceptional, in that it would allow an air current of 60 l./hr. to pass from top to base with a rate coefficient of 8 l./hr./cm., if sufficient time was allowed for adjustment. The highest air flow in the reverse direction was 15 l./hr. with a coefficient of 3.5 to 4 l./hr./cm.

For roots only, tobacco plants which had been grown in nutrient solution were planted in sand, with some of the root above the surface; the stem and leaves were removed by cutting through the root region. Also the roots of dock plants, planted in soil, were exposed; the leaves and stem were cut away and the whole was waxed over, leaving the cut surface of the root uncovered. The rate coefficient for 3 cm. of exposed tobacco root was 30 l./hr./cm.; for the dock root with cut surface alone exposed it was 3 l./hr./cm.

For leaf only, the whole of a tobacco plant was waxed over except for one leaf of about 50 sq. cm. area. Even this small area allowed air to pass through in either direction at 3 l./hr./cm.

Although different plants exhibited certain differences of behavior, the experiments established the fact that the application of relatively small pressures will permit large volumes of air to pass through plant tissues of various kinds. The particular rate coefficient may, as with zinnia, be determined by the amount of water present in the plant or soil. The size

of the plant is probably a determining factor (cf. the two tobacco plants), and so also is its age (cf. the seedlings of bean and wheat). It appears justifiable to conclude, however, that individual and specific differences in plants are largely differences of degree.

In order to test the airtightness of the wax seal around the stem and respiration chamber, tobacco plants were prepared as usual. Before the readings were observed, however, water was poured on to the top of the wax seal, making certain that the level of the water was above the level of the wax both on the stem and around the edge of the chamber. No bubbles of air came through the water, although the tests were repeated several times on different days and with different specimens. Several depths of water were tried on each occasion, and at all rates of flow from the lowest to the highest the readings were comparable to those already given, indicating clearly that no leak occurred in the wax seal, and that the air was passing through the plant.

DISCUSSION.—In these experiments no attempt was made to determine the actual path taken by the air through the plant. The experimental results are closely related to the facts demonstrated by Zimmerman *et al.* (1931) on the very rapid passage of gases, particularly ethylene, into and out of plants; to the ventilation of tree trunks, investigated by McDougal (1936); and also to the observation of Cannon (1925) in relation to roots and the aeration of soil.

The work described in this paper proves the ability of air to pass in either direction through the entire plant, and presumably through isolated or attached organs such as leaves. In the case of some plants, especially tobacco, very high rates of air passage were demonstrated with almost undetectable changes of pressure. This result was important in connection with the measurement of quantities of gases liberated or assimilated by plants.

SUMMARY

Seventeen species of plants were examined and found to permit the passage of air through their tissues both in the direction of leaf to root and root to leaf. There was an approximate proportionality between the amount of air passing and the applied pressure; and the results were reproducible. It was noted that age, size, and moisture condition of the plant were factors which appeared to affect the rate of passage. It is suggested that, while individual and specific differences occurred in ability to allow air to pass through tissues, those differences are believed to be matters of degree. The rapid passage of air through plants was demonstrated in connection with the measurement of carbon dioxide produced in respiration.

SEXUAL HORMONES IN *ACHLYA*. III. HORMONE A AND THE INITIAL MALE REACTION¹

John R. Raper

THE ACTIVITY of hormones in initiating and coordinating the sexual reproductive process in *Achlya bisexualis* Coker and *Achlya ambisexualis* Raper has been demonstrated by the writer (1939a, 1939b, 1940a). The sexual process takes place in a number of stages (Raper, 1939b), and these different stages are definitely correlated with the production and activity of the several hormones. The successive production of the different hormones and the activities which they bring about constitute a chained reaction with each stage dependent on the preceding ones. The initiation of the entire sexual reproductive process is brought about through the production, by the vegetative mycelium of the ♀, of hormone A which induces the formation of antheridial hyphae on the ♂ mycelium.

This work has suggested a number of interesting and important problems for further investigations. Of these problems, the one which concerns the ultimate identification of the active substances, is perhaps the most significant. The logical starting point for such an investigation is to determine something of the properties of hormone A, since it initiates and controls the initial ♂ reaction upon which all subsequent stages are dependent. Equally important is the incidental fact that, of the substances involved, it is the easiest to obtain in sufficient quantity for the determination of those properties.

Before the isolation of the active substance could be effectively attempted, it was necessary to work out some quantitative test for the relative concentration of the hormone in any test sample. It was also necessary to determine the effects of various environmental conditions on the response of the ♂ test plant to the active substance in order that tests could be performed under optimal conditions for all factors except the unknown variable.

The scope of the present paper is, therefore, limited to include only the production of hormone A by the ♀ plant and the physiological aspects of the production of antheridial hyphae on the ♂ mycelium in

response to this substance. From the physiological data given below the necessary standardized conditions for a quantitative test for hormone A are apparent.

MATERIALS AND METHODS.—It was shown in an earlier paper (1940a) that the ♂ plant of *A. ambisexualis* reacts more intensely when placed in the water in which a ♀ of *A. bisexualis* has grown than in the filtrate from a ♀ of *A. ambisexualis*. It has not been determined whether this is due to the greater production of hormone A by the ♀ of *A. bisexualis* or to slight differences in the chemical nature of the hormones secreted by the two ♀ plants, the ♂ being more reactive to one than to the other. That the former is the correct explanation for the different degree of effect is probable, and for the purpose of the present study the ♀ plant of *A. bisexualis* has been used exclusively as a source of hormone A and the ♂ of *A. ambisexualis* as the test plant for this substance.

Source of hormone A.—The most suitable method for obtaining a supply of hormone A has been found to be large water cultures of the ♀ fungus. For the maximum yield of the hormone it is necessary to adjust conditions so that vegetative growth is vigorous. This requires temperature of 20-25°C., the presence of trace quantities of a number of inorganic salts (Raper, 1939b), a suitable nutrient, and equally important, the absence of toxic substances. While it is not absolutely necessary to remove all impurities from the water, the yield of hormone can be increased considerably through the use of Pyrex distilled water in preparing the medium. As a nutrient, hemp seed (*Cannabis sativa*) have been found to give the most satisfactory results, the hormone content of hemp cultures being 200-1,000 per cent greater than in similar cultures in which corn, rice, lentils, starch-peptone, etc., have been used as nutrients. This fact in itself is probably significant, and may eventually aid in the identification of the substance.

Closely reproducible solutions may be obtained by using 2 gms. of hemp seed per liter of glass distilled water to which small quantities of KH_2PO_4 , MgSO_4 , CaCl_2 , FeCl_3 , and ZnSO_4 have been added. No appreciable difference has been observed in the hormone content of cultures to which split seed were added as nutrient, the mold thus having a solid substrate (approximately 1 mycelium for each 5 cc. of water), and those provided with an aqueous extract

This work was carried out in the Kerckhoff Biological Laboratories of the California Institute of Technology, Pasadena, California, during the tenure of a National Research Fellowship in Botany.

Report of work carried out with the aid of Works Progress Administration, official project No. 165-1-07-172, Work Project No. N-12165. The author wishes to express his indebtedness to Mr. Harvey W. Tomlin for his very able assistance.

of ground autoclaved seed. In the latter case it is necessary to inoculate by introducing a large number of zoospores, since the introduction of an agar block containing a few hyphal tips leads to the production of only a single spherical mycelium.

Air is bubbled through the cultures for two reasons: (1) to keep the water in constant movement so that the numerous mycelia will remain separate and (2) to provide a constant supply of oxygen which is essential for maximum growth.

Fig. 1. Graph showing the relationship of concentration of hormone A to the elapsed time of production of antheridial hyphae after immersion of δ plants of *Achlya ambisexualis* in test solutions. On the abscissa unity is the untreated filtrate from the φ of *A. bisexualis* as described in the text.

At room temperature vegetative maturity of the mycelia is reached in such cultures on the fourth or fifth day after inoculation. The concentration of hormone A increases until about the fifteenth day of incubation.

Preparation of δ test plants.—Care must be taken to secure fairly uniform δ test plants. The simplest and easiest method that has been found is as follows. Ten very small agar blocks ($1 \times 1 \times 0.5$ mm.) containing hyphal tips of the δ plant are placed widely distributed over the bottom of a Petri dish, and on each block is placed one-half of a split hemp seed. The smallest amount of water that will barely cover the bottom of the dish is added, and the culture is then incubated under the desired environmental conditions for twenty-four hours. At the end of this time the mycelia are vigorously washed with a stream of water from a wash bottle and approximately 10 cc. of water is added to each dish. After forty-eight hours additional incubation, they are approaching vegetative maturity and exhibit maximum sensitivity to the active substance.

EXPERIMENTAL RESULTS.—Two possible criteria for measuring the intensity of the δ reaction to hormone A were recognized during previous work on the hormonal coordinating mechanism in *Achlya*. The first objectives, then, were: (1) to ascertain the relationship between the quantity of hormone A present and the intensity of the δ reaction which it induced

and (2) to explore the two possible means of determining the reaction intensity.

Time of reaction.—During the investigation of the sexuality of *A. ambisexualis* (Raper, 1940b), it was frequently observed in both water and agar matings that the time which elapsed between approximation of two compatible mycelia and the initiation of antheridial hyphal production was correlated with the quantity of mature sexual organs ultimately produced. Invariably where the initiation of antheridial hyphal development was delayed more than a few hours the final production of oogonia and oospores was scant. Since subsequent stages in the sexual reaction are dependent on and doubtless limited by the intensity of the reaction, it seemed probable that the reaction time of the δ plant would vary inversely with the concentration of hormone A.

To test this possibility the liquid in a 3-liter φ culture was concentrated in a reduced pressure still to one-tenth its original volume, and from this concentrate a series of solutions was made up by dilution to contain concentrations varying from one-thousandth to ten times that of the original filtrate. Into 10 cc. of each of these solutions were placed two 72-hour δ test plants. These test plants were observed at very frequent intervals with a dissecting microscope and the time of the first appearance of antheridial hyphae for each test solution was recorded. The results of one such experiment are given in figure 1. The hypothesis advanced above was borne out in a number of such series, for in all cases the δ plants in higher concentrations of φ filtrate (containing hormone A) reacted sooner than those in lower concentrations. However, there were two objections to this method of determining hormone A concentration. (1) In all save the very lower limits of the series the reaction time is changed so little by relatively great changes in concentration of the hormone that the test is not sufficiently critical. (2) It is exceedingly difficult to determine the exact moment when the small knobs, which will develop into the thread-like antheridial hyphae, first appear on the vegetative hyphae. This difficulty is increased when an extended series of solutions is tested and the number of observations increased.

Number of antheridial hyphae.—The second possible criterion of reaction intensity was the relative number of antheridial hyphae produced by a δ test plant. In a mating of two compatible plants the relative abundance of antheridial hyphae seems to be directly proportionate to the number of oogonia and oospores finally produced. Since hormone B is secreted by the δ plant only after the production of antheridial hyphae, and in all probability produced by the antheridial hyphae themselves, subsequent reactions are probably limited by the number of antheridial hyphae produced, the number of these organs in turn being limited by the quantity of hormone A.

To determine whether this was the case, a concentration series, similar to those used in the preceding experiments and prepared from the same φ concen-

trate, was made up and into each of the solutions were placed two ♂ test plants. At the end of two hours numerous antheridial hyphae had been produced on the test plants. The average number of antheridial hyphae on 3 mm. hyphal tips of the test plants was determined for each of the several concentrations. Three millimeters was the distance selected because of differences of distribution of antheridial branches on the ♂ hyphae in reactions of high and low intensity. When the number of antheridial hyphae is small, they are almost invariably located within 0.5 mm. of the hyphal tips, whereas, when a larger number are formed, they are distributed approximately equally along the entire length of the parent hypha. Actually a count of the number along the entire hypha might give more accurate results, but such determinations are complicated by the dense and tangled growth near the substrate.

For each determination antheridial branches were counted on ten hyphal tips chosen at random on each of the two test plants. Thus an average of twenty counts was used for each test.

The relationship between the concentration of hormone A and the production of antheridial hyphae on the ♂ plant is shown in figure 2. In this figure the reaction intensity, as measured by the number of antheridial hyphae/3 mm. hyphal tip, is plotted against relative concentration of ♀ filtrate where unity is the untreated filtrate from ♀ plants as described above.

FIG. 2. Effect of hormone A concentration on the number of antheridial hyphae produced on the ♂ plant. Concentrations shown on the abscissa are identical with those in figure 1.

In lower concentrations small increases of the hormone result in considerable increases in the number of antheridial hyphae until an optimal concentration is reached at three times that of the original ♀ filtrate. That the reaction is less beyond this point of optimal concentration is doubtless due in part to an increased amount of solutes in the solutions (see below) as well as to a supermaximal quantity of the hormone. The quantity of ♀ filtrate used for each test (10 cc.) is only an arbitrary and convenient amount. The number of antheridial hyphae produced by a plant in a 1 cc. sample and that produced in 10 cc. is the same. The amount of hormone per unit

volume of water (concentration) determines the number of antheridial hyphae rather than the total amount of hormone available to the ♂ plant.

This method is preferable to that using the time interval between application of the hormone and the first appearance of visible effect for the following reasons: (1) To determine the quantity of antheridial hyphae produced it is not necessary to keep the test plants under constant observation; hence it is

Fig. 3. Effect of temperature on the initial ♂ reaction (production of antheridial hyphae). The test solution for these determinations was untreated ♀ filtrate, represented by unity on abscissae of figures 1 and 2.

possible to work with a considerably larger number of tests. (2) Greater accuracy is possible, since, in measuring reacting time, it is difficult to determine the exact moment when antheridial hyphal formation is initiated. (3) Small changes in concentration of the hormone within the critical range bring about greater percentage differences in the number of antheridial hyphae produced than in the length of time required for their initiation.

The average number of antheridial hyphae on a hyphal tip of the ♂ plant forms the basis of the quantitative determination (biological assay) of hormone A after standardization of the various environmental conditions affecting it.

Conditions affecting the reaction of the ♂ plant to hormone A.—1. *Temperature.*—The range of temperature within which ♂ and ♀ plants of *A. bisexualis* and *A. ambisexualis* give intense sexual reactions is from 23–28°C. Vegetative growth of both these species is normal over a much wider range, from 15–40°C. The rate of growth, however, becomes progressively faster the higher the tempera-

ture. It seemed, therefore, expedient to determine the relationship between reaction intensity and temperature in order to ascertain the optimal temperature for the δ reaction as well as to clarify the discrepancy between temperature requirements for sexual activity and those for normal vegetative vigor.

A series of identical test solutions, each containing two δ plants, were placed in incubators with temperatures ranging from 15 to 37°C. At the end of two hours counts, as described above, were made of the antheridial hyphae on the δ plants from the different temperatures.

Fig. 4. Effect of hydrogen-ion concentration on the initial δ reaction. The unbuffered control (untreated φ filtrate) had a pH value of 6.2 and gave a reaction of 36 antheridial hyphae/3 mm. of hyphal tip. The maximal reactions in both buffered solutions are lower than the unbuffered control, and the more strongly buffered series (M/150 total phosphate) consistently gave less reaction than the weaker buffered series (M/500 total phosphate). Any dissolved electrolyte depresses the reaction in proportion to its concentration.

The relationship between temperature and reaction intensity is shown in figure 3. At 15°C. the reaction is slight, at 25 to 30°C. an optimum is reached, and for further increases in temperature there is progressively less activity. At 37°C. the δ gives no reaction whatever.

This relationship between temperature and reaction of the δ plant to hormone A brings out a number of interesting points. The limiting effect of high temperatures in many biological reactions is caused by the permanent injury of the reacting tissue or material. Here this cannot be the case, for the maximal temperature for vegetative vigor is considerably higher than the maximal for the production of antheridial hyphae. On the other hand the limiting effect at 37°C. cannot be the destruction of hormone A, for it will withstand a temperature of 100°C. for several hours without detectable loss of activity. The question naturally arose whether the ability of the δ plant to react to hormone A was merely inhibited for the duration of supermaximal temperature or whether this ability was thereafter permanently lost. If this ability were not completely destroyed, would

the δ plants be capable of reaction immediately when returned to optimal temperature, or would re-action ability return gradually only after a lapse of time?

In order to elucidate the phenomenon the following simple experiments were performed. Several δ plants were placed in an incubator at 37°C. for five hours and then returned to 25°C. and tested immediately by immersion in 10 cc. samples of φ filtrate. Plants which had remained at 25°C. were tested simultaneously. The average number of antheridial hyphae of the plants of the two series was approximately the same, well within the limits of counting error. As a further control, two of the plants placed in the 37°C. chamber were immersed in the test solution of hormone A during heating and during this time no reaction resulted. These plants were then returned to 25°C. in the test solution and counts of the antheridial hyphae made at the end of two hours. The intensity of the reaction in these plants was approximately equal to that of the other tests and to that of the 25°C. controls.

These results show (1) that the sensitivity of the δ plant is only temporarily inhibited by supermaximal temperature, (2) that no permanent injury to the mechanism of reaction results from such heating, and (3) that there is immediate recovery of reaction ability when plants are returned to less severe conditions. It is also apparent that a close control on temperature must be maintained in order that the test might be used as a quantitative test (biological assay) for hormone A.

2. *Hydrogen-ion concentration and the effect of dissolved salts.*—Hydrogen-ion concentration within wide limits has previously been shown (Raper, 1939b) to have little effect on the entire sexual process of *A. ambisexualis*. However, for the purpose of quantitatively determining hormonal concentrations any appreciable hydrogen-ion effect should be accounted for and adjustment made to the optimal pH.

Two series were made up using untreated φ filtrate as a base. The first series contained phosphate buffers of 1/500 Molar concentration and ranging from pH 3 to 10. The second series, similar in range, contained phosphate buffers of 1/150 Molar concentration. The untreated φ filtrate, which had a pH value of 6.3, was used as a control for both series. Two 72-hour δ test plants were placed into each of the different solutions, and counts of the antheridial hyphae were made at the end of two hours.

The results of these two series of tests are given in figure 4, the relative intensity (as compared to the unbuffered control) of the reactions in the various solutions being plotted against the concentration of hydrogen-ions. The optimum hydrogen-ion concentration for the reaction lies near pH 6. This optimal pH is extremely close to that of the unbuffered φ filtrate, and of a large number of φ filtrates for which the hydrogen-ion concentrations were determined none varied from pH 6.3 by more than 0.2 units. Thus in many cases adjustment of hydrogen-ion concentration is not necessary.

In these tests another limiting effect is shown which is probably more important than the effect of hydrogen-ion concentration. A comparison of the curves in figure 4 shows that the reactions in the weaker buffered solutions (M/500) were consistently higher than the reactions for the same pH values in the stronger (M/150) solutions. Further, the maximum in each series is significantly less than that of the unbuffered control at approximately the same level of hydrogen-ion concentration. A point of complete inhibition of the δ reaction is reached before salt concentration becomes toxic to the test plants.

This depressing effect of dissolved salts complicates the determination of hormone A concentration. Many of the samples which need to be assayed for hormonal content in the course of working out a procedure for the isolation of the active substance contain salts in greater concentration than will allow of quantitative determination of the hormone. Such samples, then, must be freed of their salts before the tests are made. This can usually be accomplished by precipitating the salts by the addition of acetone in which the hormone is readily soluble, or by extracting the active component with ethyl ether. Either of these methods results in a sample sufficiently free of inhibiting dissolved inorganic compounds to be assayed directly.

3. *Variation in sensitivity of δ plants.*—One of the first experiments performed on the φ filtrate was to determine the stability of the hormone over a period of time. In tests made at four-hour intervals δ plants showed progressively less reaction during one day. The same φ filtrate tested the following day with plants from the original δ culture induced reactions at first equal to the maximum of the day before, the reactions of the δ plants then decreased at subsequent times of testing. These observations indicated a diurnal rhythm in sensitivity of the δ plants to the hormone. However, preliminary experiments showed that the time of maximum sensitivity varied from day to day. A similar condition has been known for years in the reaction of *Avena* coleoptiles to auxins (Kogl, 1933; Kogl, Haagen-Smit, and van Hulssen, 1936; Juel, 1936. Cited in Went and Thimann, pp. 49-51, 1937). A comparison of the variation curves of *Achlya* sensitivity has been made with those of *Avena* tests performed concurrently by Went *et al.* Although the curves of variations of the two plants are similar they do not "fit," for the maxima in the two cases occur at different times and the lengths of time for the complete cycles in the two tests are also different.

Since the reaction of the δ plant to the same φ filtrate varies so drastically from one time to another and the rhythm is not a rigid 24-hour one, the quantitative test for hormone A must also be standardized in respect to that variation. The ideal solution to the problem would be the discovery of means of eliminating or at least reducing the variation to a low percentage of the maximal reaction. With this

objective in view a number of environmental factors have been eliminated as the controlling agents.

Naturally the first factors to be suspected were light and temperature. Accordingly δ test plants were grown and tested in a room with continuous orange light, the temperature being constantly maintained at 25°C. The first day's tests under these conditions showed the inadequacies of these measures,

Fig. 5. Variations in the intensity of reaction of δ plants of *A. ambisexualis* to a standard solution of hormone A during 96 hours. Cultures of the δ test plants used in this series were made at noon three days before they were used in the tests, and the change to new plants was made each day at 12:00 midnight. It is apparent from the curve above that small differences in the age of the δ plants affect neither their activity nor the variations of their response to hormone A at different times.

for the variations were as great as at room temperature with alternating light and darkness. Stock δ cultures were then grown under these conditions for a month and subcultures were then tested in portions of φ filtrate at four-hour intervals for 96 hours. The results of these tests are shown in figure 5. During the 96-hour period five complete cycles were observed, an average of nineteen hours between comparable points on the different cycles. On the third day of the experiment the average number of antheridial hyphae was 12.4 at 4:00 P.M., and eight hours later at 12:00 midnight a reading of 24.1 was recorded, an increase of almost 100 per cent. Even greater variations have been repeatedly observed in a single sample of φ filtrate.

Next in the order of suspects was the effect of minor changes in the concentration of noxious gases in the atmosphere. The first experiments to determine whether or not changes in the air were responsible for the variation were performed in the following manner. Male test plants were grown in each of two constant temperature rooms (25°C.). In one of the rooms the air stream from the air conditioning system was passed through a charcoal filter while in the other room the air was unfiltered. Tests were then

made in the usual manner at intervals of three hours during a 24-hour period.

The plants in each of the two rooms varied in their reaction to the standard hormone solution, the variations reaching a maximum of 140 per cent. The shapes of the two curves fit closely, although the series of plants in the room with the filtered air was uniformly slightly higher than in the room with the untreated air.

Since there was an appreciable difference in the two series indicating that composition of the air affected the test it seemed desirable to extend the study. Plants were then grown in a closed chamber into which thoroughly washed air was led from a tank; thus during the experiment there would be no variation in the composition of the air around the cultures. The plants grown under these conditions were then tested in the constant air chamber at four-hour intervals concurrently with controls outside.

Again the reactions of the two series followed the usual pattern varying considerably during the period of testing, but with only minor differences between the reactions of plants of the two series at any one time.

By this time it was apparent that the rhythmic variation of sensitivity of the δ plants was not to be eliminated by simple control of environmental factors. During the time occupied by the preceding experiments the cycles of variation were found to be very irregular. At one time an average of seventeen hours elapsed between maximum reactions, at others as high as thirty hours elapsed. Since the variation could not be eliminated the next best solution to the problem was to stabilize its cycle at twenty-four hours so that quantitative tests could be made at the same time on different days. Two attempts to accomplish this end were made.

The first was to grow and test the δ plants in a constant temperature room (25°C.) with twelve hours of brilliant illumination alternating with twelve hours of total darkness. Plants grown and tested in constant temperature and continuous orange light were used as controls. For a 48-hour period of testing there was no difference in the reaction of the plants of the two series. During this experiment the variation of both controls and alternating dark-light plants followed a 24-hour cycle, but it must be considered as coincidental since the cycle of variation under constant illumination varies from seventeen to thirty hours.

A second attempt was then made to stabilize the cycle at twenty-four hours. The heating unit of a 25°C. room was equipped with a time switch, so that during twelve hours the temperature remained at 25°C. but dropped to approximately 20°C. for the alternating twelve hours. The lighting arrangement was left as in the preceding experiment with brilliant illumination during the period when the temperature remained at 25°C. and with the room in darkness when the heating unit was shut off. Male plants were then grown and tested under these conditions each day for five consecutive days. A small degree of success

was achieved by these measures, for the first test made after the temperature was brought up to 25°C. each day was the highest for that day with a rapid decrease in antheridial hyphae at subsequent times of testing. However, the difference between the maxima of the several days was still too large to use the number of antheridial hyphae directly as a measure of hormone concentration. Further work in which the temperature is more drastically changed and better controlled might possibly result in the complete stabilization of the cycle on a 24-hour basis. This has not yet been attempted.

It has been clearly shown above that, although environmental conditions may affect the sensitivity of δ plants, controlled conditions of the test will not eliminate the cyclic changes.² Apparently the variability is an inherent property of the plant and is affected only indirectly by external conditions. The quantitative test for hormone A is further complicated, since it has not been possible either to control or to stabilize the variation of the δ plant.

Two means of dealing with the situation have been used and both are inadequate. Tests to give quantitative results should be made while the δ plants react with maximum sensitivity. Such a procedure is obviously impractical, since the time of the variation cycles also varies.

"Calibration" of the δ plants by means of a standardized solution containing hormone A has been used. When the variation from maximum sensitivity is slight such a method is satisfactory, but its accuracy decreases with greater variations, for the relationship between the number of antheridial hyphae and the concentration of hormone A is not a linear function at any concentration level of the hormone. Thus it has been necessary to repeat those tests in which the reaction is less than 50 per cent of the maximal. When frequent tests are made the time of maximal sensitivity is approximately known for each day and the number of repeat tests is not excessive.

The biological assay and definition of the physiological unit of hormone A.—It has been shown above that the intensity of reaction of the δ plant to hormone A is influenced by a number of environmental conditions in addition to the amount of hormone A present. These factors then must be standardized if a test for activity is to be quantitative.

A physiological unit of hormone A is that amount of hormone/cc. required to produce an average of ten antheridial hyphae/3 mm. of vegetative hyphal tip of 72-hour test plants (1) at the time of maximal δ sensitivity, (2) at 25°C., (3) with the pH adjusted to a value of 6.0, and (4) in the absence of inhibiting salts.

The original untreated φ filtrate used in the tests to show the relationship between hormone concentration and reaction intensity contained, on the basis of

² After the completion of the work dealt with in this paper a means of controlling this variation has been found. This control and related matters will be described in a future account.

this definition, 18 units of hormone per cc. Thus the concentration of hormone which induces the maximal reaction in the δ plant is 50 to 60 u/cc. of test solution. However, at this level changes in concentration bring about very small differences in the number of antheridia. The curve is much more critical at lower concentrations. The standard solution used to "calibrate" the plants in quantitative tests contained 6 u/cc. the lowest value in the critical portion of the curve where counting error could be kept below 5 per cent.

EFFECTS OF KNOWN CHEMICAL COMPOUNDS.—Hormone A is secreted in very small quantity by the φ plants of *A. bisexualis* and in exceedingly low concentrations brings about the production of antheridial hyphae on δ plants. Because of the small quantity of the hormone produced by the φ plant, the difficulties of obtaining sufficient material for chemical work were recognized at an early stage of this work. During the past two years approximately a hundred plant and animal tissues and products have been tested in the hopes of finding another source of the material. The results in all cases have been negative. When the number of materials tested and the chemical richness of certain of them (i.e., urine, yeast extract, hay infusion, etc.) are considered, it is clear that the substance responsible for the reaction of the δ plant is no commonly occurring compound. The continuation of testing materials at random might eventually locate a source of the hormone, but enough have already been tried to make this procedure of doubtful value.

In addition to natural products a large number of known and chemically pure compounds have also been tested for activity. Two groups of compounds have been found in which certain members show some activity.

The saturated dicarboxylic acids comprise the first of these groups. Those containing from 2 to 10 carbon atoms have been tested. Three of these, malonic, glutaric, and pimelic acids, induced the formation of a limited number of antheridial hyphae. The number of antheridial hyphae produced in each case was small, but there was no doubt as to their identity as such. Of these three the reaction given by glutaric acid was the most intense, while the reactions given by malonic and pimelic acids were slightly less and approximately equal. It is remarkable that each active member has an odd number of carbon atoms in the chain and that the longer odd-numbered as well as all of the even-numbered members were inactive. A number of closely related acids have been tested, fumaric, maleic, malic, tartaric, and citric, and in all cases the results were negative. That none of the three active acids is identical with hormone A is certain, for in each case (1) the reaction is always slight, an average of 10–15 antheridial hyphae/3 mm. of hyphal tip being exceptional; (2) relatively high concentration (1 mg. to 10 cc. water) of the acids is necessary to get a reaction, and higher concentrations are toxic; and (3) the relationship of activity to pH is different from that of hormone A. For

pimelic acid the maximum lies at 4.5, for glutaric acid at 4.0 and for malonic acid at 3.5.

More significant than the effect of these three acids on the δ plant is their effect on the φ plant. When small quantities of either glutaric or malonic acid are added to the medium in which φ plants are grown, hormone A production is increased in proportion to the amount of acid added (fig. 6). A maximal effect

Fig. 6. Graph showing the effect of glutaric acid on the production of hormone A by the φ plant of *A. bisexualis*. These determinations of hormone concentration were made five days after the cultures were started. The concentration of hormone reaches a maximal value only after twelve to fourteen days' incubation of the cultures. The addition of malonic acid to the culture medium of the φ plant has a similar and slightly greater effect on hormone A production than glutaric acid.

is reached when 25 to 35 mg. are added to a liter of culture medium. A culture to which glutaric or malonic acid has been added in this concentration after growing a week contains frequently ten to fifteen times as much hormone A as a control culture lacking the acid. When the cultures are allowed to remain undisturbed for a longer period of time this increase continues until the cultures are about two weeks old, the hormone concentrations sometimes reaching almost a hundred times that of the control. The greatest concentration of hormone A yet attained has been in ten- to twelve-day-old 18-liter cultures with the φ plant growing on halved hemp seed and with 400 mg. of malonic acid added to each culture. In 80 cultures of this kind the average concentration of hormone was 1,330 hormone units in each cubic centimeter of filtrate. That it is an actual increase in hormonal concentration in the φ filtrate is shown by adding the acid to the control φ filtrate and immediately testing the mixture. Then the number of antheridial hyphae which are produced is less than the number that can be accounted for by the two factors separately. The acid is apparently used in the synthesis of the hormone. Whether it enters directly into this process or affects the process indirectly is not known.

Certain members of the second group, barbituric acid and related compounds, show much more activity when tested with ♂ plants than any of the dicarboxylic acids. Barbituric acid and hydantoin induce activity of low intensity. A number of substituted derivatives of barbituric acid have been tried in the test. Certain of these derivatives were completely inactive, while others induced much more intense reactions than unsubstituted barbituric acid. Actually one of the derivatives of the acid induced in the ♂ plant the most intense reaction yet seen, but a relatively high concentration (10^{-5}) of the compound is necessary before any reaction results.

Too few of the derivatives of barbituric acid have been tested as yet to correlate activity in inducing the formation of antheridial hyphae definitely with any particular structure or grouping of constituents within the molecule. The investigation of these compounds, however, is being continued and will be given in detail in a future account.

The barbiturates, unlike the active dicarboxylic acids, have no apparent effect on the ♀ plant and the production of hormone A.

SUMMARY

Techniques are described for culturing the ♀ plant of *Achlya bisexualis* as a source of hormone A and the preparation of ♂ plants of *A. ambisexualis* as test material for the ♀ hormone.

The relationship between hormone concentration and the activity of the ♂ plant has been determined. The number of antheridial hyphae produced in response to the hormone furnishes a satisfactory index of the reaction intensity, the number of antheridial hyphae being proportionate to the concentration of the hormone. A less critical test is the length of time required by the ♂ plant to initiate the production of antheridial hyphae. This method has been rejected because of the difficulties of determining the exact time of the initiation of the reaction.

The reaction of the ♂ plant is limited by a number of factors in addition to the concentration of hormone in the test solution. Optimal conditions of temperature and hydrogen-ion concentration have been determined. Light has no apparent effect on the reaction. Dissolved inorganic salts in the test solution have a depressing effect, and the reaction can be completely inhibited by increasing their concentration. The ♂ plant is shown to vary considerably in its sensitivity to hormone A, the variation being very irregular. Attempts to eliminate or minimize this variation as well as attempts to stabilize the variation cycles at twenty-four hours have been unsuccessful.

Standardized conditions are described for the quantitative determination (biological assay) of hormone A and the activity or physiological unit of the hormone is defined.

The effects of certain pure chemical compounds on the ♂ plant of *A. ambisexualis* and the rate of hormone A production by the ♀ of *A. bisexualis* are described and briefly discussed.

EMBRYO CULTURE AN EFFECTIVE TECHNIQUE FOR SHORTENING THE BREEDING CYCLE OF DECIDUOUS TREES AND INCREASING GERMINATION OF HYBRID SEED ¹

W. E. Lammerts

ARTIFICIAL CULTURE of embryos in nutrient solutions has long been practiced. Hannig (1904) showed that after a certain stage of development unripe seeds of Crucifers may be removed and brought to maturity by artificial culture. Dieterich (1924) repeated and extended these experiments to include species in other families, and Laibach (1929) showed its advantages by successfully growing embryos of flax hybrids which ordinarily abort if left

¹ Received for publication July 12, 1941.

Grateful acknowledgment is made to H. B. Tukey who kindly supplied me with the information available in 1936 and to the Armstrong Nurseries for providing facilities and growing the seedling trees.

to ripen on the plant. Tukey (1933) applied the technique to the germination of early sweet cherry embryos which usually abort, and later (1934, 1938) reported successful culture of peach, apple, pear, and plum embryos. LaRue (1936) cultured immature embryos of *Lactuca*, *Taraxacum*, *Chrysanthemum* and *Zea*. Blake (1939) outlined a method of embryo culture different from that of Tukey and successfully cultured over 1,000 hybrid peach seedlings, many from varieties which normally have partially shriveled embryos difficult to germinate by ordinary stratification methods. Approximately 75 per cent of these seedlings fruited three years after the crosses were made.

In most of the above experiments, the artificial culture technique was mainly of value as a means of growing immature or anomalous embryos and defective seeds. During the past five years while developing a fruit-breeding program at Armstrong Nurseries, Ontario, California, several thousand peach, nectarine, and apricot seeds were artificially cultured. Germination and subsequent growth was compared with that obtained by the usual methods of stratification. The following data are presented to show that embryo culture may effectively be used in large scale commercial fruit breeding to shorten greatly the breeding cycle of deciduous trees and markedly increase the germination of hybrid seeds. Certain problems yet to be solved are discussed and suggestions made which may lead to their solution.

MATERIALS AND METHODS.—*Culturing of embryos.* In general the methods described by Tukey (1934) were used. However, the following changes in culturing technique were helpful in avoiding failures:

(1) The pits were removed from ripe fruit, sterilized in mercuric chloride 1–1,000 and stored at room temperature for three to four weeks before culturing the embryos.

(2) Hot water was used to make the calcium hypochlorite disinfecting solution.

(3) The embryos were then sterilized by placing them in this solution which was heated to 110° to 115° F. Thorough but gentle shaking and stirring of the solution is necessary to remove air bubbles from the surface of embryos. A surface tension reducer such as the 10 per cent Aerosol O. T. C. powder used at the rate of 1 gram per liter is helpful if the embryos are badly infected by fungi on the testas.

(4) A .9 per cent agar solution was used to avoid softening during hot weather. Bacto-Difco agar and Baker's chemicals were used.

(5) Vitamin B₁ at the rate of 1 mg. per liter proved helpful in stimulating root formation. Instead of glucose, .5 per cent sucrose for mature and 2 per cent for immature embryos was used.

(6) The culture bottles were placed in standard flats to a depth of about ½ inch in a layer of wet peat. They were then placed under greenhouse benches in subdued indirect light.

Methods used in growing of seedlings and young trees.—The embryos began to grow soon after placing them in the culture bottles and in two or three weeks were usually large enough to transplant. Meanwhile river sand was treated ten to fourteen days earlier with 5 per cent ethyl mercuric iodide² at the rate of ½ gram per square foot (Lammerts, 1940). The seedlings were removed from the bottles with forceps, separated from the agar, and planted in 1½-inch thumb pots. These were then plunged in moist peat in flats and protected the first few days by inverting a wet flat over them, raising one end to a low angle.

In about three more weeks the seedlings were transplanted to three-inch pots. A compost of ½ loam,

²Obtained from Du Bay Chemical Company under the name of Du Bay 1155 HH.

⅓ sand, and ⅓ peat, which had been treated one week earlier with 5 per cent ethyl mercuric iodide at the rate of 1½ grams per square foot, was used. The seedlings were grown in these pots until the primary bark showed through in cracks at the base of the stem. They were then gradually hardened off by decreasing soil moisture and lowering the night temperature to 45° F. By November 1 growth had stopped, and shoots were sufficiently hardened to place the seedlings in a dark cold storage room at 40° F. After three to six weeks, depending on the type of hybrid, all leaves dropped off and plants were completely dormant. When they were removed to the greenhouse, growth was rapidly resumed and in a few weeks a shift to four-inch pots was necessary. By using a balanced nutrient solution the seedlings were grown to a height of 3 to 4 ft. in these pots. After hardening off in the lathhouse they were transplanted to the field in April or May during cloudy weather so as to avoid burning of the tender leaves. The seedlings were placed 4 ft. apart in the rows and the rows 4 ft. apart to allow for proper cultivation. They were furrow irrigated once per week, and liberally fertilized with ammonium phosphate (16–20) in July.

GERMINATION RESULTS.—Cross pollination of peach and nectarine varieties was begun in the spring of 1936. Approximately half of the seeds obtained from crosses involving the early mid-season peach varieties, Babcock and Early Imperial, as female parents were embryo cultured about three weeks after the fruit was ripe, that is about August 1, 1936. The remaining seeds from these crosses were stratified at 40° F. in flats of moist sand for three months. Of the 124 seeds from the Babcock crosses, 121 (or 98 per cent) germinated and grew into trees following embryo culture. Of the 111 stratified seeds, 97 (or 88 per cent) eventually germinated and survived. In the case of the Early Imperial crosses 189 of the 200 embryo cultured seeds, or 94 per cent, germinated and survived, as compared with only 57 of the 124 stratified seeds, or 46 per cent. Furthermore, many seedlings from both the Babcock and Early Imperial crosses did not emerge following stratification until April, and some did not come up until May, 1937. The germination results following stratification compare favorably with those reported by other investigators (Crocker and Barton, 1931) who reported an average of 41 per cent germination following stratification in peat at 5° C. for three months.

The seedlings from embryo-cultured and stratified seed obtained from these experiments were separately labeled and grown under as nearly comparable conditions as possible. They were lined out in May, 1937, and grown under comparable field conditions. Comparative data on the fruiting and flowering of these seedlings will be presented in a subsequent section.

In 1937, 45 different crosses of peach, apricot and nectarine varieties were made which involved 16 varieties as female and 21 varieties as male parents. About 10,500 flowers were emasculated and polli-

nated resulting in 2,536 fruits, an average of 24 per cent set. Only $1\frac{1}{2}$ per cent of the pollinated flowers set in the cross of Millers Late \times July Elberta³ and $8\frac{1}{2}$ per cent in the cross Sims \times July Elberta. In crosses such as these, and even for average cases, a high germination percentage is important, as large numbers of fruit can only be obtained by making many cross pollinations, an expensive and time consuming process. Accordingly all the seeds from the 1937 crosses were embryo cultured. Striking varietal differences in response of embryos to culturing were shown.

The embryos in 204 pits were so defective and shriveled as to be incapable of germination, while 15 pits had two kernels, thus making a net loss of 189. The completely shriveled embryos were mostly found in the following crosses:

	Pits with aborted embryos	Total pits
Mayflower \times July Elberta.....	112	150
Sims \times Transvaal Cling.....	10	175
Early Imperial \times Vainqueur..	11	81
Early Imperial \times July Elberta	7	102

Both Mayflower and Early Imperial are early types and characteristically have abortive embryos. Sims usually has a small percentage of fruit with split pits containing aborted embryos.

Of the remaining 2,347 embryos cultured, 593 failed to germinate. These with the exception of Mayflower \times July Elberta looked completely normal when cultured. In fact many partially shriveled embryos which seemed non-viable, germinated readily. The failure of the normal appearing embryos is most puzzling and merits careful study. They were found mostly in crosses involving Babcock, Lukens Honey, Early Imperial, and Rio Oso Gem as female parents. An average of 40 per cent of the embryos from these varieties failed to germinate. The percentages varied from 82 per cent failure in the case of the 1937 crosses of Babcock \times Vainqueur to 19 per cent in Rio Oso Gem \times Vainqueur. There was no relationship between the degree of earliness of the female parent and the percentage of failure. The 1938 group of embryos from Babcock \times Vainqueur germinated much better than the ones in 1937, possibly because they were cultured immediately after harvesting. This suggests that seed dormancy had begun in 1937 and that by culturing before ripening of the fruit, some of these embryos could be germinated. It is in line with this idea that the cotyledons of many of these embryos spread at right angles to the central axis and turned green. In some cases a slight epicotyl growth began. In recent experiments a few of these partially developed embryos were placed in cold storage at 40°F. for six weeks while still in the culture bottles. Upon removal to the

³ The female parent is given first in all crosses discussed in paper or listed in tables.

greenhouse some of them grew into normal seedlings.

Seven of the crosses made in 1937 involved nectarines both as male and female parents and in all cases the germination was high, averaging 82 per cent, as compared with an average of 69 per cent for the entire group of pits. The peach \times nectarine seedlings were above average in vigor.

In the spring of 1938, 1,228 cross pollinations were made resulting in 658 fruit, a 53 per cent set. This high percentage of set is due to the use of Babcock or its hybrids in most of the pollinations (table 1). The Babcock peach sets a high percentage of blossoms per tree as compared with varieties such as Sims, Lukens Honey, or Rio Oso Gem, and transmits this tendency to many of its hybrids. As will be shown later (table 3) the numbered seedlings listed in table 1 were from the 1936 hybrid seed embryo cultured August 1, 1936. It may thus be readily seen that many hybrid trees from crosses made in the spring of 1936 were used either as male or female parents or selfed in the spring of 1938.

The nectarine and double flowering characters in the peach are due to recessive factors. As both nectarines and double flowering peaches set very few fruit, it is necessary to use the F_1 hybrids of commercial peaches with nectarines and double flowering peaches as female parents when backcrossing. Accordingly, the fact that trees from embryo-cultured seeds are large enough to be used effectively as female parents two years after making original crosses is particularly important as a means of shortening the time involved in breeding new varieties of nectarines and double flowering peaches.

In 1939 approximately 2,900 self and backcross pollinations involving 32 selected hybrids from 1936 and 1937 crosses were made. These resulted in 1,114 fruit, a 39 per cent set. A total of 1,092 embryos were obtained from these fruit of which 900 or 81 per cent were successfully cultured. Nine of the hybrids involved nectarines, and it was again noted as was found in 1937 and 1938, that a high percentage of seeds from F_1 peach \times nectarine hybrids germinated and grew into very vigorous seedlings.

In the fall of 1940 an attempt was made to find a method of germinating seeds as rapid and efficient as embryo culture but involving less effort. Since only five weeks of growing time are lost in order to break dormancy of embryo-cultured seedlings and induce them to resume growth, any other method equally efficient can only allow for a similar period of time for cold storage treatment. Accordingly half the pits from eight different F_1 hybrid trees were stratified beginning August 30, 1940, for five weeks in moist sand at 40°F. They were then cracked and the kernels planted in small pots of treated soil which were placed in the greenhouses. The remaining half of the pits were cracked and embryo cultured on August 30, 1940. Although in one case 60 per cent germination was obtained following stratification and pericarp removal, the average germination was only about half that obtained following embryo culture (table 2). In some cases germination was very poor and the

Totals	1,228	658	638	470	Ave. % 76

^a An understanding of the seedling numbers listed in this table is necessary in order to understand the significance of the data. Thus in group 2, the backcross 36057/4 × Early Double Flowering Red indicates that seedling 4 in population 57 obtained by crossing Babcock with the Early Double Flowering Red peach in the spring of 1936 was used as a female parent in the spring of 1938.

TABLE 2. *Comparative germination of peach seeds, embryo-cultured and stratified August 30, 1940. The pits were stratified in sand for five weeks at 40°F., pericarps then removed, and kernels planted in pots of treated soil. The records were completed December 6, 1940.^a*

few seedlings which did emerge by December 6, 1940, were weak and slow growing. Obviously five weeks is not sufficient time for proper chilling of pits, though only three to five weeks is sufficient to break dormancy of seedlings from non-after-ripened seeds.

COMPARATIVE BEHAVIOR OF TREES FROM STRATIFIED AND EMBRYO CULTURED SEEDS.—The most outstanding results were those obtained with apricots. This species seems particularly well adapted to embryo culture technique, both as regards high percentage of germination and rapid vigorous seedling growth. By October 1, 1937, plants from embryos cultured in June were 1½ ft. high and ready for cold storage treatment at 40° F. Six weeks' storage was sufficient to satisfy their chilling requirements, for upon removal to the greenhouse they rapidly started growing again and continued growth until November, 1938. Many of these trees flowered and bore fruit in the spring of 1940, thus establishing a three-year breeding cycle for the apricot.

As shown in table 3, 91 per cent of the peach trees from seeds cultured August 1, 1936, flowered in the spring of 1938, two years from the time of hybridizing, while only 55 per cent of the trees from stratified seeds flowered. Almost twice as many trees in the embryo-cultured group bore fruit. Even more important from the breeding point of view was the greater number of flowers per tree. Accordingly many more fruit were set. Thus in the cross of Babcock × Early Double Flowering Red the average was 79 fruit per tree in the embryo-cultured group as compared with only 37 fruit per tree in the group from stratified seeds. For Babcock × Early Double Flowering Pink the ratio was 31 to 13. Several trees in the embryo-cultured group bore over 170 fruit and six others bore more than 100 fruit per tree. These trees, then, were satisfactory for selfing and as female parents in backcrossing as shown by results presented in table 1. Often 100 per cent of the selfed and hybrid seed from these and other two-year-old embryo-cul-

tured trees were germinated, thus supplying genetically random samples.

DISCUSSION.—Since embryo culture is a somewhat expensive method of germinating seeds, it is of interest to consider to what extent simpler methods may be used without decreasing the efficiency of the breeding program. Crocker and Barton (1931) and Flemion (1936) report from 27 to 87 per cent germination of varieties such as Elberta following pericarp removal and stratification of kernels in moist peat at 40° F. for ten to fourteen weeks. These germination results are comparable to those obtained by embryo culture. However, a period of six weeks to three months elapses before the kernels complete germination following stratification. Thus, in many cases six months of growing time are lost, and the young trees do not grow large enough to form flower buds by the following fall. A two-year breeding cycle is thus not possible. However, where rapid life cycles are not genetically important, removal of pericarp and stratification at 40° F. for ten to fourteen weeks is the simplest and least expensive method of germinating peach and other deciduous seeds.

Flemion (1934) has also found that if both pericarp and inner seed coats are removed and the seeds mixed with moist peat moss and kept at 25° F., germination occurs in five to seven days. From 37 to 94 per cent germination was obtained by this method, which is of course a simplified type of embryo culture, involving much less effort than when sterilized nutrient agar is used. The resulting plants are dwarfed in growth character, and require a period of three to five weeks of chilling before normal growth is resumed. It is important, as noted by Flemion, that injury to embryos be avoided, for fungi quickly attack the injured areas, decay sets in, and the embryos die. It is very difficult to avoid slight injuries, and so it is doubtful if high percentages of germination, especially of slow or weak embryos, can consistently be obtained by this method. In cases where hybrid

seeds may be fairly easily obtained and very high germination percentages are not genetically necessary, this method is very useful, inexpensive, and fully as rapid as the nutrient agar method of embryo culture.

It is quite important, when heterozygous varieties such as Babcock are used, that every potentially viable seed be germinated, for weak embryonic types may have characteristics of great horticultural value when matured into trees. Furthermore, a sound genetic analysis of horticulturally valuable types is dependent on securing random samples, which in turn depends on high or at least representative germination percentages. An interesting horticultural example is that of the saucer peach reported by Lesley (1939). Here the germination of saucer seeds was so low following ordinary stratification methods that the dominance of the saucer character was not at first suspected.

The higher percentage of embryo-cultured trees in bloom, as well as the greater abundance of flowers and heavier set of fruit, is not merely due to increased size of the tree, for some of the control trees from stratified seeds were fully as large as those from embryo culture. Even these, however, had very few flowers as compared with similar sized embryo-cultured trees. Evidently the application of cold treatment to satisfy the chilling requirements of seedlings from non-after-ripened seeds in some way causes the seedling trees to flower and fruit earlier and more abundantly than the same or even twice as much cold treatment applied to dormant seeds.

A further indirect advantage made possible by embryo culture is the saving in time and space needed for determining tree and fruit characters. As was mentioned above seedling trees were lined out four feet apart in the row and rows spaced four feet apart. This compact planting plan was possible because readings could be made the first spring after lining out on chilling requirements of the trees and later in the summer on such fruit characters as adherence of flesh to pit, color of skin and flesh, and shape of fruit. Accordingly, most of the trees could be re-

moved by the end of the second year, thus allowing ample room for growth of remaining seedlings and final selection three years after embryo culturing of the seeds.

SUMMARY

Embryo culture, as compared with usual stratification methods, results in a much higher percentage of germination in most apricot and peach crosses, thus giving a better random sample of genetic diversity.

Intermediate early types such as Early Imperial and hybrids ripening from the end of June until August characteristically have many abortive embryos which do not respond to stratification. These can be successfully germinated by embryo-culture methods.

In some crosses a large percentage of normal looking embryos was found which would not respond to embryo culture. The occurrence of these is not related to earliness of female or pollen parent. Some of these embryos can be germinated if given a cold storage treatment of six weeks at 40°F. while still in culture bottles.

Hybrid trees can be brought into flower two years from the time of cross pollination. Self pollinations and both male and female backcrosses can then be made every two years. These trees come into bearing two years from the time of harvesting the hybrid fruit, thus making it possible to take readings on such fruit characters as adherence of flesh to pit, skin and flesh color, and chilling requirements. Removal of undesirable seedlings by the end of the first year in the field row is thus possible.

An important saving of space is effected because the early removal of many seedlings allows the use of a four-foot square planting plan, without crowding of final tree selections.

Certain modifications in embryo-culture technique which have been found useful in avoiding failures are presented.

A NEW SPECIES AND VARIETY OF *SCLEROCACTUS* FROM ARIZONA¹

Elzada U. Clover

SCLEROCACTUS havasupaiensis sp. nov. Simplex cylindricus erectus vel curvatus, 1.5–4.2 dm. altus, 8–11. cm. crassus; areolis subrotundis; costis 13–18, tuberculis prominentibus, spinis lateralibus 6–13, ra-

Fig. 1. *Sclerocactus havasupaiensis* Clover, sp. nov. Actual type specimen photographed in natural habitat at Havasupai Canyon, Arizona (Clover 5229 in part: there are several cotypes).

diatis, flexuosis, albidis, apice adustis, 10–20 mm. longis; centralibus 4–9, flexuosis, angulatis, curvatis, summis 3 compressis, pellucidis, ascendentibus, curvatis, 4–4½ cm. longis; inferioribus angulatis, purpureo-fuscis, 6–7 cm. longis; floribus in axillis summis, numerosis (vel usque ad 30), 3–5½ cm. longis, 3 cm. crassis, 5-seriatis; segmentis 2¾–3 cm. longis, apice obtusis, brevi-apiculatis, crassis; exterioribus in media parte atro-purpureis, margine albis; interioribus albis sed deorsum viridiusculi-luteolis visis; stylo viridi-luteo, 2 mm. crasso, glabro, stigmati-

lobis viridi-luteis, 6–8, deliquescentibus; filamentis numerosis, delicatis, viridi-luteis, antheris lutei-aureis, stylo brevioribus; fructibus carneis, purpureis, sed postea siccantibus. Specimen typicum siccatum ex loco dicto "Havasupai Canyon," Arizona, conservatum est in Herbario Universitatis Michiganensis (Clover 6404). Specimen vivum est in Horto Botanico Universitatis Michiganensis, Ann Arbor, Michigan.

Plant solitary, reaching a height of 42 cm., diameter 8–11 cm.; ribs 13–18 often spiraled, prominent, usually 1 cm. high, more or less tubercled; areoles subcircular, 7–12 mm. apart and alternating with those of adjacent ribs; glands in groove above young areoles well developed, 1–3 or sometimes as many as 6, yellowish to red, exuding considerable sweet, clear nectar; young seedlings 1 cm. in diameter bearing both radial and well-developed central spines; radial spines on mature plants 6–13, usually about 10, white with dark tips, flexuous, terete to flattened, acicular, 10–20 mm. long, lateral radials usually longer than upper and lower ones; central spines various, 4–9, often with upper ones ascending, straight, flattened and translucent, 4–4½ cm. long, sometimes resembling radials, lower centrals curved or hooked, flexuous, angled, extending variously, the longest 6–7 cm., always hooked and usually pointing downward, reddish, variegated red and white to

Fig. 2. *Sclerocactus havasupaiensis* Clover sp. nov. Two specimens in natural habitat on top of Supai sandstone formation showing association with *Agave utahensis*, *Rhus trilobata*, *Coleogyne ramosissima*, *Ephedra* and certain grasses.

almost black; flowers campanulate, appearing near the apex in upper part of the areole, as many as 30 buds and flowers at one time; flowers 3–5½ cm. long, 3 cm. across; perianth segments in 5 whorls, the two outer with segments short and obtuse, margins whitish with purple-drab shading to greenish up trace, inner segments entire, yellowish-green at base fading to almost white toward tip, 2–3 cm. long, 1½ cm.

¹ Received for publication November 17, 1941.

Papers from the Department of Botany and the Botanical Gardens, University of Michigan, no. 793.

broad below the middle; scales on the ovary few, conic with rounded base, scarious, brown up trace, deciduous, 2 mm. long and containing sparse wool in axil; filaments extremely delicate, pale green, anthers bright orange, stamens shorter than the style, style 2 mm. in diameter, pale yellowish-green, stigma lobes 6-8, about the same color as style, glabrous, deliquescent, lobes appearing paired when immature, $3\frac{1}{2}$ mm. long, blunt-tipped; flowers remaining open several days, faintly scented; fruit about 1 cm. long, oblong, turning purplish but drying later; seeds shiny black, tuberculate, $2\frac{1}{2}$ -3 mm. long, much larger at upper end, hilum lateral, large, subcircular, much depressed. The type specimen (fig. 1) was collected by William Belknap, Jr., April 26, 1941, on top of the Supai Formation in Havasupai Canyon, Arizona, where the species grows abundantly. Specimens not in flower were previously collected by the author in July, 1940, in Havasupai Canyon (Clover 5229) near Navajo Falls, and in Hualapai Canyon (Clover 5100) on talus of the Supai Formation. A few plants were seen on the floor of Cataract Canyon above Supai, September, 1941.

This cactus more closely resembles *S. parviflorus* Clover than other species, but differs from it in several respects. The general appearance is less shaggy, and the central spines are more delicate and less flattened. Of the radial spines the lower ones are the longest in *S. parviflorus*. This new species usually has the lateral radial spines longer than the lower ones. Inner perianth segments of the Colorado River species are phlox purple; style and stigma lobes are also purple. The Supai species has whitish inner segments shading to yellowish-green below. Style and stigma lobes are pale yellow-green.

SCLEROCACTUS HAVASUPAIENSIS Clover var. **roseus** var. nov. Floribus roseis, suaveolentibus; segmentis perianthii oblongis, acuminatis; stylo viridi-luteo, 1 mm. crasso, glabro, stigmatibus purpureo-rubris, acuminatis. Specimen typicum legit E. Clover & Wm. Belknap, Jr. (Clover 6403), in Havasupai Canyon, Arizona, siccatum est in Herbario, Universitatis Michiganensis.

Similar in habit to typical *S. havasupaiensis*; flowers pale rose-pink with inner segments shading to pale yellow-green at base, decidedly sweet-fragrant; inner segments oblong, tips acuminate; style pale yellowish-green, stigma lobes reddish-purple, tapering toward the tip, not appearing paired when immature, not deliquescent; seeds with prominent tubercles. This variety was found in association with *S. havasupaiensis* on top of the Supai Formation in

Havasupai Canyon, Arizona, April 26, 1941. Young seedlings were growing at the base of the plants. Additional plants were collected by C. F. Shaffer, Jr.,

Fig. 3-4. *Sclerocactus havasupaiensis* var. *roseus* var. nov. Actual type specimen (Clover 6403) photographed while alive at Botanical Garden, University of Michigan, now dried and preserved as a herbarium specimen. Additional plants of the same collection (cotypes) are in the living collection (Bot. Gard. no. 18079).

in the same location in May, 1941, and are in the living collection (no. 18079) in the Botanical Gardens, University of Michigan.

A NEW FUNGUS BELONGING TO THE CLADOCHYTRIACEAE¹

Leland Shanor

AS RECENTLY summarized by Berdan (1941), the family Cladochytriaceae includes eight well recognized genera. The sporangia of six of these genera dehisce following the gelatinization of the tip of the exit papillae, while the sporangia of the other two genera are operculate.

In the inoperculate group are included the genera *Cladochytrium* (Nowakowskii, 1877), *Amoebochytrium* (Zopf, 1884), *Physocladia* (Sparrow, 1932), *Catenaria* (Sorokin, 1876), *Mitochytridium* (Dangeard, 1911), and *Physoderma* (Wallroth, 1833). The thalli of species of *Urophlyctis* (Schroeter, 1889) and of *Physoderma* are so much alike that most critical students of the family are more or less agreed that at present the criteria for separating these genera are superficial and inadequate. In the operculate group there are two genera, *Nowakowskiella* (Schroeter, 1897) with three species, and *Septochytrium* (Berdan, 1939), a monotypic genus. The species of *Nowakowskiella* at present accepted are: *N. elegans* (Schroeter, 1897), *N. ramosum* (Butler, 1907), and *N. profusum* (Karling, 1941a). The chytrid described as *Nowakowskiella endogena* Constantineanu by Domjan (1935) is probably the same as the species first described from India by Butler (1907) and just recently reported from Texas by Karling (1941b). The present paper reports a new species belonging to the Cladochytriaceae which is tentatively being placed in the genus *Nowakowskiella*, although the type of resting spore formation in this new species is fundamentally different from that of any of the other species of the genus.

During the course of my examination of various types of bait that had been placed in water samples collected from pools and streams of eastern Illinois, I have encountered numerous chytridiaceous fungi, one of which is of particular interest. This chytrid was first isolated on cellophane as recommended by Haskins (1939). The water samples from which it was obtained were taken near Penfield, Illinois, in the fall of 1940. It was collected again during the early summer of 1941, from Crystal Lake, Urbana, Illinois, likewise growing on cellophane bait that had been placed in a water sample. In addition to cellophane as a substratum, other materials have been used with success. Growth of the fungus on portions of grass leaves or corn seedling leaves, and on filter paper or lens paper as recommended by Couch (1939) has been quite extensive. Growth on plain agar is sparse.

Unifungal cultures of this chytrid have been maintained on various types of substratum for over nine months, and observations indicate that growth on all is more or less uniform. The principal differences are produced by growth on cellophane where the cultures are less extensive, more compactly developed, have more swellings, and a larger percentage of inter-

calary sporangia and resting bodies. The following description of this species is based primarily on cultures growing on sterilized corn seedling leaves.

The resting bodies of this fungus, particularly those with more than one resting spore, bear a superficial resemblance to oogonia containing mature oospores, such as are found in certain other aquatic Phycomycetes. Resting spores are in no sense oospores, as is seen from their developmental stages, and their true nature is discussed in another part of this paper. The majority of resting bodies contain but a single resting spore which is somewhat flattened on one side so that it is more or less hemispherical in shape. Therefore, the name *Nowakowskiella hemisphaerospora* is proposed for this new species.

Nowakowskiella hemisphaerospora sp. nov.—Rhizomycelium much branched, extensive, hyaline, filaments quite variable in diameter, spindle shaped or oval swellings numerous or very much scattered. Zoosporangia usually terminal on short lateral branches or occasionally intercalary, smooth, hyaline, operculate, quite variable in shape and size but commonly ovoid, ellipsoid, or pyriform, usually $7.5\text{--}14.2\ \mu \times 9.5\text{--}28.4\ \mu$ (commonly $11.5 \times 17.2\ \mu$) with one to several exit papillae (or tubes), apical, subapical, or lateral, varying in length up to $18\ \mu$ and usually about $4.0\text{--}4.7\ \mu$ in diameter; operculum circular, $3.1\text{--}3.5\ \mu$ in diameter, either remaining attached to the sporangium or lying loose nearby. Zoospores hyaline, spherical or ovoid, $4.4\text{--}6.3\ \mu$ in diameter, with a single refractive globule; cilium attached posteriorly, $32.5\text{--}40.0\ \mu$ in length. Resting bodies terminal or intercalary, usually somewhat ellipsoidal, containing one to four thick-walled hyaline resting spores and a corresponding number of empty cells. Resting spores rather uniform in size, $8.5\text{--}12.6\ \mu \times 11.6\text{--}15.6\ \mu$ (commonly $11.0 \times 14.2\ \mu$) usually somewhat hemispherical in shape; refractive globule in mature resting spores large with several smaller ones commonly surrounding it. Germination unknown.

Nowakowskiella hemisphaerospora sp. nov.—Rhizomycelium copiose ramoso, extenso, hyalino, filamentis diametris variis, incrementis fusiformis aut ovatis, multis vel permultis dissipariis. Zoosporangiis plerumque terminalibus in ramo lateralis vel nonnumquam intercalaribus, levibus, hyalinis, operculatis, forma atque magnitudo vario, saepe ovoideis, ellipsoideis, aut pyriformibus, plerumque $7.5\text{--}14.2\ \mu \times 9.5\text{--}28.4\ \mu$ (plerumque $11.5 \times 17.2\ \mu$), cum papillis exeuntibus (vel tubulibus) una vel compluribus, apice aut sub apice aut a latere formato, variatis longitudine usque ad $18\ \mu$, atque plerumque $4.0\text{--}4.7\ \mu$ diametro; operculo orbiculato, $3.1\text{--}3.5\ \mu$ diametro, aut sporangio affixo aut liberato adiacente. Zoosporiis hyalinis, sphaericis vel ovoideis, $4.4\text{--}6.3\ \mu$ diametro, cum refractivo globulo singulo; cilio posteriore affixo, $32.5\text{--}40.0\ \mu$ longitudine. Truncis perdurantibus aut terminalibus aut intercalaribus, aliquid ellipsoideis,

¹ Received for publication July 23, 1941.

uno ad quattuor sporiis perdurantibus parietibus crassis, hyalinis, atque aequalis numerarum vacuum cellarum contineriis. Sporiis perdurantibus relativo constanti magnitudine, $8.5-12.6 \mu \times 11.6-15.6 \mu$ (plerumque $11.0 \times 14.2 \mu$) plerumque aliquantenus hemisphaericis, refractivis globulo magno in sporiis maturiis cum parvis globulis plerumque circumvaleris. Germinatione incompta.

spicuous refractive globule, typical of a chytrid zoospore. After an active swimming period these zoospores become rather sluggish, move about in an amoeboid fashion for a while, and finally settle down on the substratum to germinate. A single germ tube is commonly developed (fig. 4) which soon produces rhizoids and branches to form the rudiments of the rhizomycelium (fig. 5). Usually a spindle-shaped

Note that the number of empty cells in F and G corresponds to the number of developing resting spores. A $\times 380$, all others $\times 570$.

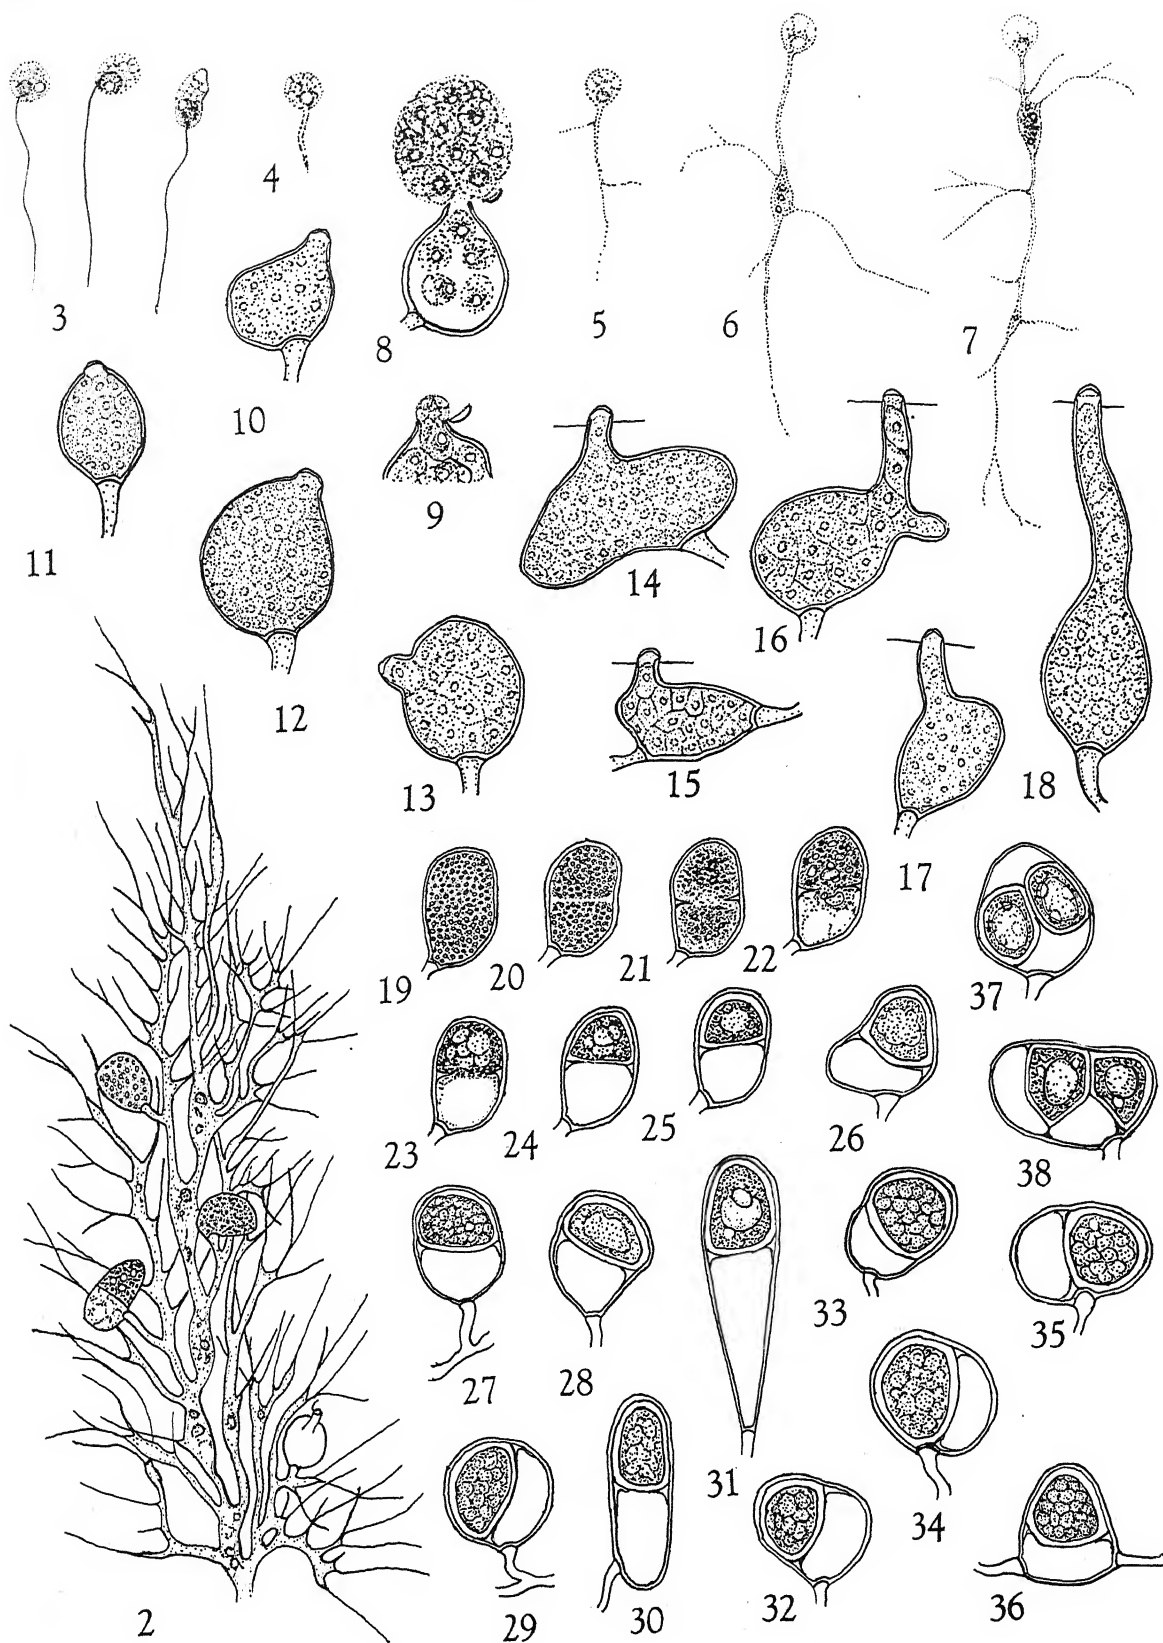

Collected as a saprophyte growing on cellophane placed in water samples taken near Penfield, Illinois, October 5, 1940, and isolated in the same manner from water samples from Crystal Lake, Urbana, Illinois, by the author, May 25, 1941, and from Dixon Spring, Illinois, by H. W. Larsh, June 12, 1941.

This fungus is quite distinct from any of the known Cladochytriaceae, and is easily distinguished from other species of *Nowakowskiella* by its characteristic resting bodies which always have been found in abundance.

DEVELOPMENT OF THE THALLUS.—The zoospores of *N. hemisphaerospora* (fig. 3) are characteristically globular in the swimming stage with a con-

swelling develops in the germ tube before much branching has taken place (fig. 6, 7). The nucleus from the spore migrates into this spindle swelling. This change in the position of the nucleus is easily demonstrated in cultures growing on cellophane by the addition of cotton blue to a preparation. In unstained material, several small refractive globules are prominent in each spindle-shaped swelling. In the filamentous rhizomycelium these refractive globules are absent or extremely small and the cytoplasm appears almost homogeneous, having a somewhat gleaming cast.

As the rhizomycelium becomes more extensive, the principal filaments become thicker with much irregularity in width and with many swellings in the older

portions (fig. 1A, 2). The swellings may be fusiform or more or less globose or elongate. Numerous rhizoids arise along the filaments and these terminate in very fine points. I have been unable to obtain even the slightest indication of a positive reaction for the presence of cellulose in the walls of any portion of the thallus with chloro-iodide of zinc.

The sporangia and resting spores most frequently arise at various places on the rhizomycelium on the ends of the short lateral branches (fig. 1, 2, 8, 10-14, 16-35, 37, 38). Intercalary sporangia (fig. 15) and resting bodies (fig. 36) have been observed frequently, but these are decidedly fewer in number than those produced terminally.

Sporangia formed extramatrically are, for the most part, pyriform, obpyriform or somewhat globose in shape with short exit papillae (fig. 1B, C; 8-13). There is ordinarily just a single papilla on extramatrical sporangia, and this is usually almost apical in position. Subapical and lateral papillae, however, are not uncommon.

Intramatrical sporangia (fig. 14-18) vary more in shape and size than do those produced extramatrically. Exit tubes are also much longer than the exit papillae of extramatrical sporangia. The fundaments of several exit tubes may be formed by a single sporangium or the single tube may have one or more prominent diverticulae which resemble papillae (fig. 16). As far as I have been able to observe, only one papilla is functional. The length of the exit tubes is determined by the depth at which sporangia are formed below the surface of the substratum. The tip of the tube never has been observed to protrude much above the substrate surface.

Sporangial proliferation occurs in *N. hemisphaerospora*, but is quite rare and not nearly as common as it is in species of *Cladochytrium* (Nowakowski, 1877; Karling, 1931; Berdan, 1941).

Stages in sporangial development of *N. hemisphaerospora* are identical in their main features with those of typical chytridiaceous fungi. These protoplasmic changes have been described by others (Berdan, Couch, Karling, Sparrow, etc.) for developing sporangia of several species of the Cladochytriaceae and of the Rhizidiaceae, so need not be repeated in detail here.

When sporangia of *N. hemisphaerospora* are mature and zoospores are discharged, the operculum is either carried away by the emerging spores (fig. 1B, 8) or is pushed to one side and remains attached to the margin of the orifice (fig. 1C, 9). The presence of an operculum on all sporangia was at first a point in question, for it was found attached to only a rather

small percentage of the empty sporangia. Observations on developmental and germination stages of many sporangia, however, revealed the fact that the operculum is frequently completely detached and is moved away some distance from the sporangium.

Here, as in other chytrids where the necks of the emergence tubes are rather narrow, the orifice through which the spores escape is smaller in diameter than are the normal spores. Therefore, as the spores escape from sporangia, they become elongate as they move into the exit tubes and emerge (fig. 9), but assume the globular shape soon thereafter (fig. 8). The zoospores of *N. hemisphaerospora* are held together by a hyaline matrix for a short while after emergence and are not enclosed in a vesicle as reported for *Physocladia* by Sparrow (1932).

RESTING SPORE FORMATION.—The resting bodies of *Nowakowskella hemisphaerospora* are formed by the thallus at the same time that zoosporangia are being produced or even before zoosporangial formation begins. Often very young thalli may have several developing resting bodies before any zoosporangia have reached maturity. However, as a thallus becomes more mature, the production of resting bodies far surpasses the formation of zoosporangia.

The majority of resting bodies arise as terminal enlargements of short lateral branches of the main filaments of the rhizomycelium, but some have an intercalary origin. In early stages of development, young resting bodies can hardly be distinguished by their shape and size from early stages in sporangium formation. The protoplasm of young resting bodies, however, is much more dense and contains many more minute refractive globules than do young sporangia.

With the exception of those that are of an intercalary origin, resting bodies arise in most cases without any definite relationship to the swellings of the rhizomycelium. Most of the resting bodies are of a rather uniform size and contain at maturity a single thick-walled resting spore (fig. 1E; 25-36). The larger resting bodies may contain as many as four resting spores. Resting spores, whether produced singly (fig. 25-36) or with others in a resting body (fig. 37, 38), are of a relatively uniform size. When more than one resting spore is formed in a resting body, the individual resting spores are slightly smaller than the average size of those formed singly. Within the walls of each resting body, accompanying the resting spores, are empty cells, thought to be "male" cells, whose protoplasm has previously united with that of each cell which matured to form resting spores.

Fig. 2-38.—Fig. 2. Portion of thallus growing on cellophane to show characteristics of rhizomycelium.—Fig. 3. Zoospores.—Fig. 4-7. Germinating zoospores in various stages of development.—Fig. 8. Zoosporangium showing spores being discharged into a matrix.—Fig. 9. Tip of sporangium showing emergence of a spore through the orifice of exit papilla.—Fig. 10-13. Extramatrical sporangia showing typical shapes and various positions of exit papillae.—Fig. 14-18. Intramatrical sporangia. Fig. 16 shows a diverticulum from the point of origin of the exit tube.—Fig. 19-25. Stages in formation of a resting spore.—Fig. 26-35. Various shaped resting bodies which contain single resting spores illustrating positions that resting spores may occupy within resting bodies.—Fig. 36. An intercalary resting body with a single resting spore.—Fig. 37-38. Resting bodies with two resting spores and two empty cells in each. (Fig. 2, $\times 438$; all others $\times 850$.)

Young resting bodies arising in a terminal position at first enlarge in a globose fashion but soon become elongate (fig. 19). Elongation very frequently takes place in such a manner that the long axis of the resting body is more or less at right angles to the stalk. The protoplasm that has been accumulating in the developing resting body is considerably more granular and more dense than in any other part of the thallus. Many small refractive globules also accumulate in these developing resting bodies.

As development progresses, a hyaline central region becomes evident in young resting bodies indicating that the protoplasm has undergone cleavage (fig. 20). The two parts thus formed are of approximately the same size. Between these two protoplasts an incomplete wall is deposited which separates them, except in the center where the wall is not deposited until later (fig. 21). During the formation of the wall, the refractive globules in each cell begin to coalesce and those in one cell become increasingly fewer (fig. 22). The movement of the protoplasm from one cell to the other is very gradual and takes at least twelve to fourteen hours; consequently, it is very difficult to observe the actual movement of the protoplasm. It can be readily observed, however, that the protoplasm in one cell becomes more vacuolate as the protoplasm in the other becomes more dense. The amount of refractive material also becomes more abundant in the cell in which the protoplasm is accumulating (fig. 22, 23). When practically all of the protoplasm has moved from one cell into the other, the cell that contains the dense protoplasm forms a thick wall. This wall is always fused with that of the resting body so that the spores within never lie entirely free. The refractive material in the thick-walled cell continues to coalesce until one large globule with several smaller ones can usually be observed in each mature resting spore (fig. 24, 25).

As far as can be observed in living material, the stages in development of the several-spored resting bodies of *N. hemisphaerospora* are essentially like those of resting bodies in which a single resting spore is formed. The fusion of the different pairs of cells in the developing several-spored resting bodies takes place more or less simultaneously and the resting spores reach maturity at approximately the same time. The germination of resting spores has not been observed.

As yet no detailed study has been made of the nuclear behavior in resting spore formation in *N. hemisphaerospora*, but observations on cultures growing on cellophane that have been stained with cotton blue indicate that a nuclear fusion may occur. By the time cleavage of the protoplasm within a resting body has taken place, each cell contains a single nucleus. Later stages in development have two nuclei in one cell and none in the other, while the mature resting spore appears to be uninucleate. The passage of nuclei from one cell to another or the actual fusion of the nuclei has not been observed in the material fixed and stained to date, but it appears that with proper diligence these stages could be

found. In resting bodies containing more than two cells, each cell is also uninucleate in early stages, and the same is true of the mature resting spores.

DISCUSSION.—It appears that the type of resting spore formation observed in *Nowakowskiella hemisphaerospora* is unique for the Cladochytriaceae. The cells that fuse are formed by the cleavage of one protoplast and are approximately equal in size. Although mature resting spores may resemble oospores, the fusion process is not oomycetous.

The hemispherical or flattened resting spores of species of *Urophlyctis* may appear similar in some respects to the resting spores of *N. hemisphaerospora*. Some authors have considered this characteristic shape of the resting spores of *Urophlyctis* of sufficient importance to warrant the retention of *Urophlyctis* as a genus distinct from *Physoderma*. The resting spores of *Urophlyctis* have been thought by some to develop following a conjugation of similar cells and Schroeter (1897) included this genus, along with certain other chytridiaceous fungi in which sexuality was known or suspected, in his newly created family, the Oochytriaceae. *Nowakowskiella hemisphaerospora* could not be included in the genus *Urophlyctis* in our present system of classification because of its operculate sporangia. In the Chytridiales, whether sporangia are operculate or inoperculate is a taxonomic character of fundamental importance.

Certain of the resting spores of *Nephrochytrium stellatum*, described and figured by Couch (1938), appear similar to the typical resting bodies of *Nowakowskiella hemisphaerospora*. His figures 25 to 29 also indicate a similar development to that of the single-spored resting bodies of *N. hemisphaerospora*, but nothing of the nuclear behavior is discussed. Couch points out that the resting bodies of *N. stellatum* resemble the azygospores of certain of the Mucorales. It might be noted here also that the azygospores of *Azygozygum chlamydosporum* Chesters (1933) rather superficially resemble the single-spored resting bodies of *Nowakowskiella hemisphaerospora*. The azygospores of *Azygozygum*, however, are multinucleate structures.

SUMMARY

A new species of the genus *Nowakowskiella* is described. It is characterized by a rather extensive rhizomycelium, operculate sporangia which lack an apophysis, and by resting bodies that contain one or more resting spores which are formed following the fusion of paired protoplasts. This fungus grows saprophytically on cellophane, on boiled grass or corn seedling leaves, and other similar substrata. It is distinguished from other species of the genus by the numerous resting bodies which, as a rule, contain a single hemispherical, hyaline, smooth-walled resting spore. Resting bodies, however, may contain up to four resting spores.

The cytology of resting spore formation has not

been studied in detail, but there is some evidence to indicate that a nuclear fusion may occur in the formation of the resting spores.

A DEVELOPMENTAL ANALYSIS OF CELL LENGTH AS RELATED TO STEM LENGTH¹

Elizabeth A. Bindloss

INTEREST IN the problem of cell size and its relation to organ size in plants was first stimulated in the latter part of the nineteenth century by the investigations of Sachs (1893), Amelung (1893), Frank (1895), and Gauchery (1899). These investigators attempted to determine whether a positive correlation existed between the size of the organ and the size of its constituent cells at maturity. Such studies failed to recognize the changes in size relationships of cell and organ which occur during ontogeny. It is only within the past decade that the developmental aspects of the problem of cell and organ size have been considered.

The present investigation has had as its object the analysis of the changes in cell lengths in the embryonic region of the stem apex and their relation to stem length at successive stages of the plant's vegetative development. The study has been extended to include a comparison of cell lengths in genetically tall and dwarf varieties of the same plant species in order to determine whether a positive or negative correlation exists between plant height and the

length of the embryonic and elongating cells in the shoot apex. Such a developmental analysis of the growth of immature cells, on which genes presumably exert their greatest influence, should throw further light on the rôle played by those genetic factors which directly or indirectly control the ultimate size of cells and organs.

MATERIALS AND METHODS.—Good material for a study of cell-organ size relationships is found in the stem tip, where cells by their continual division and elongation give rise to the fundamental structure of the plant axis and its associated organs. Growth of the stem in most cases is strictly polar, and its cells are likewise polarized in their elongation parallel to the stem axis. Sierp (1913) in his studies of genetically tall and dwarf plants emphasized the importance of using cell length rather than cell width or volume in any investigation of the relationship of cell size to plant height. Thus in the present study cell length is used as a measure of cell size in analyzing differences in height between tall and dwarf plants in which height is controlled by genetic factors.

Preliminary investigations of genetically tall and dwarf varieties of *Antirrhinum majus*, *Phlox Drummondii*, *Salvia splendens*, *Ageratum Houstonianum*, *Verbena hybrida*, *Tagetes patula*, *Petunia hybrida*, *Lycopersicum esculentum*, *Zinnia elegans*, and *Pi-*

¹ Received for publication October 9, 1941.

The writer wishes to express her sincere appreciation to Professor Edmund W. Sinnott for his helpful advice and criticism during the course of the investigation and to both Professor Sinnott and Professor George S. Avery, Jr., for their suggestions during the preparation of the manuscript.

sum sativum showed that certain of these plants were not favorable for a developmental study of cell size in relation to height. Suitable material was provided by *Lycopersicum esculentum* and *Zinnia elegans*, for in these plants the prominent main axis of the plant enabled overall height to be measured accurately, the plants grew rapidly, and the seed size was sufficiently large for the embryo to be removed *in toto* from the seed coat.

Fig. 1. Distribution of seed weights of Marglobe (tall) and Dwarf Stone tomatoes.

Two commercial strains of *Lycopersicum esculentum* were studied. Marglobe is a tall variety, homozygous for the height factor *D*. Dwarf Stone, homozygous for the dwarfing factor *d*, has the characteristics described for such tomato plants by MacArthur (1926). The stems are shortened and stocky; cotyledons, leaflets and petioles short and broad; leaves somewhat puckered and downcurved and foliage deeper green in color than that of the Marglobe variety. Leaf number in Marglobe and Dwarf Stone was the same in each of the stages studied, but stem diameter was greater in Dwarf Stone. Differences in stem length of the two varieties appeared as early as the cotyledonary stage.

The zinnia varieties Giant and Lilliput were studied. Giant normally grows to 2½ and 3 feet, while Lilliput grows to about 1 foot. Breeding behavior of these zinnias indicates that height is due to multiple factors (Burpee, 1940). The two varieties resemble each other closely in leaf size, shape, and number. At maturity, however, flower size was somewhat greater in the Giants than in Lilliputs. A greater mean seed weight (determined after removal of the pericarp) in Giant plants is associated with their larger flower size.

Because of conflicting reports concerning the effect of seed weight on plant height, it seemed advisable in a study of tallness and dwarfness to use

seeds of tall and dwarf plants which were essentially equal in weight. Therefore, all seeds were weighed singly on a Roller-Smith precision balance. Observed height differences then might be expected to be due to inherent differences in the plants' developmental patterns rather than to an advantage on the part of one plant brought about by greater "capital" in the embryo. Before weighing the zinnia achenes, the outer husk or pericarp was removed.

The distribution of tomato and zinnia seed weights is shown in figures 1 and 2. It was found that the modal class of the Marglobe seeds was from 2.2 to 3.4 mg.; and of the Dwarf Stone seeds from 2.4 to 3.6 mg. The seeds in these two groups were planted, for all practical purposes the difference in the two groups being so slight that they may be considered essentially equal. In zinnias, the modal class for Giant seeds was 4.0 to 5.5 mg.; and for Lilliputs 3.5 to 5.0 mg. These were the classes used. There was a much greater elimination of large and small seeds than in tomato as is indicated by figure 2.

All seeds were planted in flats of garden soil the first of July. The zinnias were transplanted into adjacent field plots fifteen days later; the tomatoes four weeks later. In so far as possible the tall and

Fig. 2. Distribution of seed weights of Giant and Lilliput zinnias.

dwarf plants used in this study were grown under identical conditions. In the tomatoes, where the variability in height was slight, 100 plants were measured in the early stages of development, but fewer were measured at each successive stage as the number became reduced. The minimum number of tall or dwarf plants measured at any one time was 50. Because the zinnias were more variable in height in the early stages of growth, 150 plants were used in determining overall mean height. These measurements began when the hypocotyl was 3 to 5 mm. above the ground and were continued approximately every five days thereafter.

Of the stem tips collected for histological study, those representing four stages in the vegetative ontogeny of the plant were arbitrarily selected for further investigation. These stages for tomatoes were (I) the dormant embryo; (II) 7-day-old seedlings; (III) 23-day-old plants; and (IV) 38-day-old plants. Zinnia plants at stages comparable to II, III, and IV were 9, 15, and 22 days old. Stage III was selected as being intermediate in point of time between the seedlings and the oldest plants. Stage IV included plants selected five days before the first flower primordia were visible.

All stem tips were killed in CRAF solution, dehydrated by the butyl alcohol method, and embedded in paraffin. Longitudinal serial sections were cut at a thickness of 8μ . Five individual stem tips of both tall and dwarf forms were studied at each developmental stage mentioned above. On each slide bearing a single stem tip at least five sections were approximately median. In each of these five sections, cell lengths of a series of successive cells were measured, proceeding in a proximal direction from the stem apex (see fig. 3). Since there were five stem tips of each stage and separate determinations were made for five median sections of each, the mean length of each cell in the series was based on 25 measurements. Thus the mean length of the first cell at the apex was determined by 25 measurements, the second cell by 25, etc. Cell lengths were measured with an ocular micrometer (oil immersion objective) and converted to microns. A total of approximately 35,000 cells was measured.

Of the cells in the shoot apex, usually the first ten, forming the promeristem, were isodiametric and non-vacuolate. Cells beyond this region are in various stages of vacuolation. In the embryos and seedlings of both zinnias and tomatoes the 50th cell from the

Fig. 3. Diagram of a typical terminal meristem showing a series of successive cells.

tip was relatively mature and had almost reached its maximum length. However, in later stages it was necessary to extend the region of cell measurement in order to find cells which were of constant length. All of the cells measured, with the possible exception of the older cells in the seedling hypocotyl, were embryonic in the sense that they were located in a region where cell division is still going on, *i.e.*, mitotic figures were discernible.

OBSERVATIONS.—HEIGHT OF TOMATOES AND ZINNIAS.—Marglobe and Dwarf Stone tomatoes showed visible height differences when the hypocotyl first appeared above the ground. The greater height of the Marglobe plants was maintained throughout all

later stages of development as is shown in figure 4. When plotted logarithmically the height measurements of the two varieties lay along two parallel straight lines. Thus the rate of stem elongation is the same for each variety.

The initial differences in hypocotyl lengths of the Marglobe and Dwarf Stone seedlings suggested that their height differences were already present in the

Fig. 4. Height of Marglobe and Dwarf Stone tomatoes grown in soil. Roman numerals show successive stages of development at which cell lengths were determined.

seed or established at some time between seed dormancy and the appearance of the seedling above the soil. Dormant embryos of the two varieties, dissected from seeds of the same weight, also showed differences in length: embryos of Marglobe tomatoes were 1 mm. longer than Dwarf Stone embryos. When the two kinds of seeds were germinated on filter paper the Marglobe hypocotyls were always longer than those of Dwarf Stone until growth ceased (fig. 5). Thus tallness or dwarfness in tomatoes is already established in the seed and is not solely a function of later development.

Although Giant and Lilliput zinnias ordinarily show a marked difference in height, under the conditions of the present investigation such plants exhibited little or no height differences during vegetative growth. When the flowers were fully formed, however, the Giant plants were taller than the Lilliputs. Figure 6 shows the height of zinnias at successive stages in development. Bailey (1939) stated that it was necessary to plant zinnias early in the season in the North in order to obtain specimen plants 3 feet tall. Since the zinnias of this study were not planted until July 1, it is possible that the tall zinnias, which

are especially sensitive to length of day, failed to develop to their fullest extent.

The weight of the seeds may be a more significant factor than the environment of these plants in deter-

Fig. 5. Height of Marglobe (tall) and Dwarf Stone tomatoes grown on filter paper.

mining their height. The seeds of Giant and Lilliput zinnias, selected for planting, were of approximately uniform weight. However, in the entire sample 48.7 per cent of the Giant seeds were heavier than those in the modal class while only 13.5 per cent of Lilliput

Fig. 6. Height of Giant and Lilliput zinnias grown in soil. Roman numerals show successive stages of development at which cell lengths were determined.

seeds were heavier. Conversely 35.2 per cent of Lilliput seeds were lighter than those of the modal class, whereas only 11.4 per cent of the Giant seeds weighed less. Thus in selecting seeds of similar weights, the relatively *large* Lilliput seeds were planted and the relatively *small* Giant seeds.

In the tomato varieties Marglobe and Dwarf Stone there was little difference in the normal distribution of the respective seed weights (fig. 1). Thus, although there may be a positive correlation between seed weight and plant height, it could not be demonstrated by the use of these tall and dwarf varieties. It seems probable that such a correlation may exist in zinnias and that the relatively heavy Giant seeds ultimately produce taller plants than do Lilliput seeds. If this is true, then the selection of seeds of nearly uniform weight would result in the similar heights of both "tall" and "dwarf" plants as observed in this investigation.

Fig. 7. Diagrams of growing points of Marglobe and Dwarf Stone tomatoes and Giant and Lilliput zinnias at four stages of development. $\times 60$.

MERISTEM SIZE IN TOMATOES AND ZINNIAS.—Observations of median longisections of typical meristems of zinnias and tomatoes at four stages of development (fig. 7) showed no striking differences in the meristem sizes of tall and dwarf forms. There seems to be, therefore, no correlation between meristem size and plant height. This is in agreement with the observations of Bindloss (1938) in which no relationship was found between meristem size and the respective vigor of inbred and hybrid maize plants. In the tomatoes there was a tendency for the meristems to be a little broader in the dwarf variety.

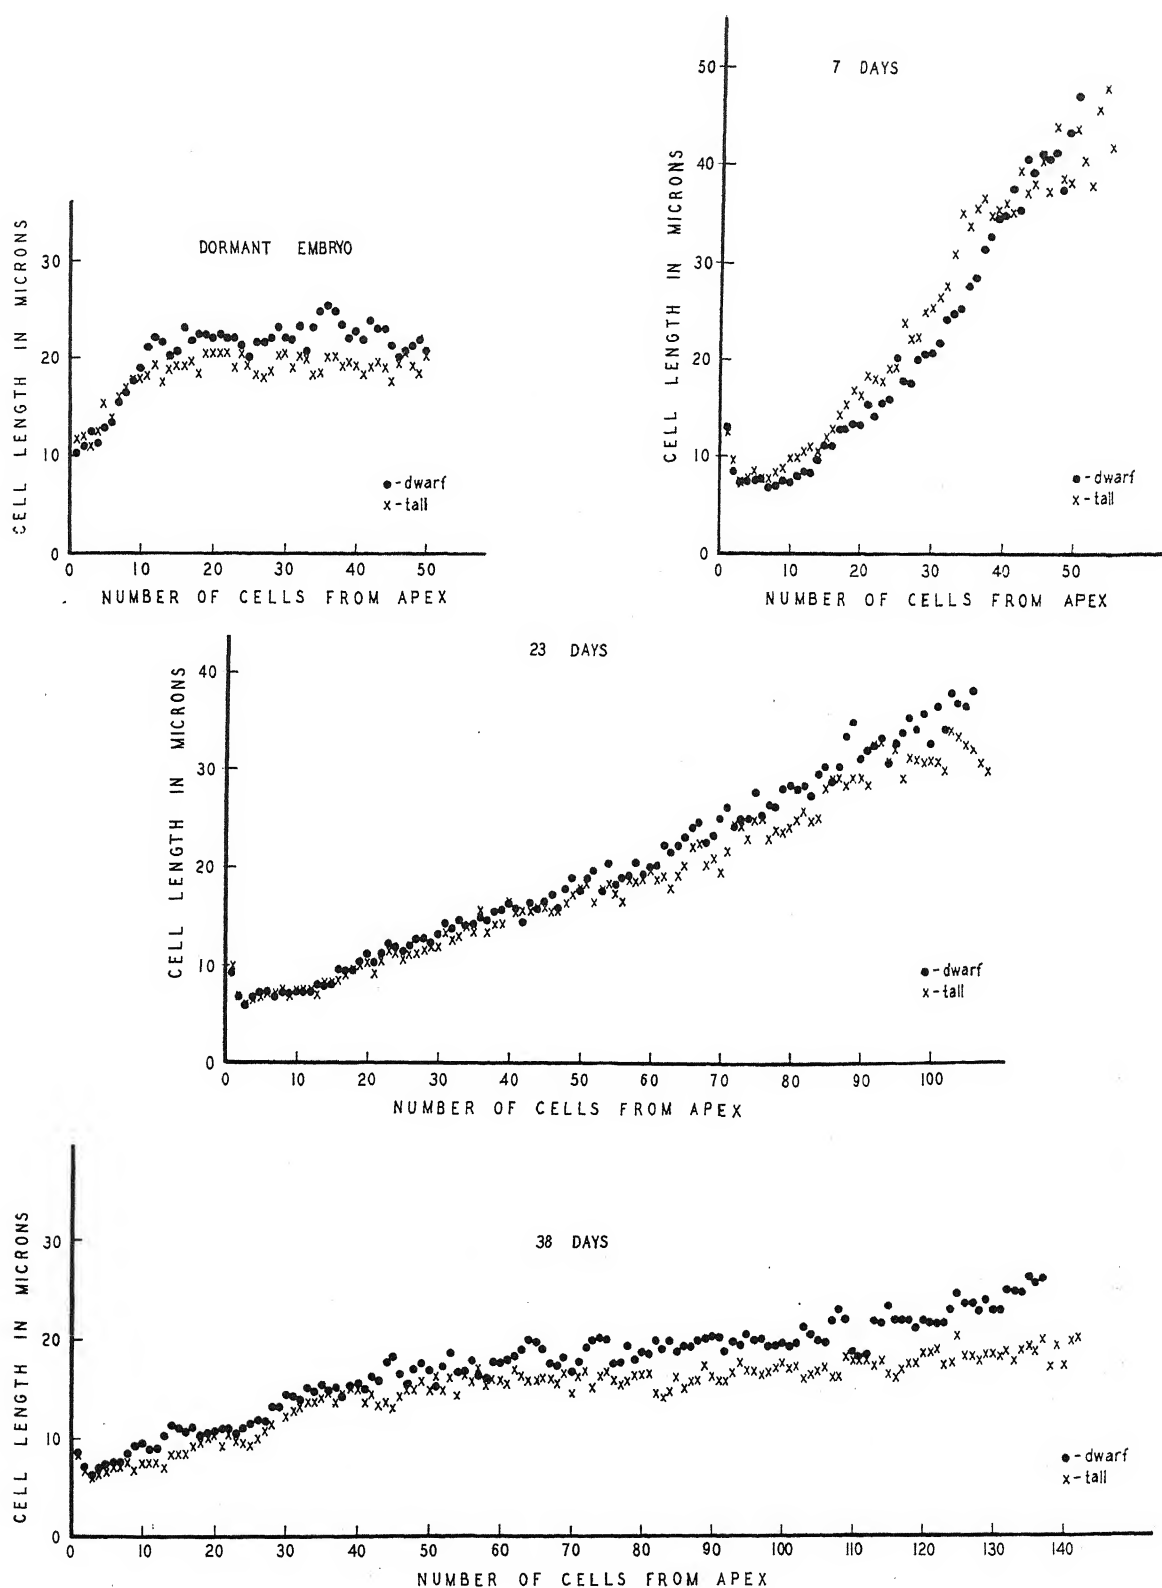

Fig. 8-11. Successive cell lengths in the terminal meristematic regions of Marglobe and Dwarf Stone tomatoes.—Fig. 8 (upper left). Dormant embryo.—Fig. 9 (upper right). Seven-day-old seedlings.—Fig. 10 (center). Twenty-three-day-old plants.—Fig. 11 (below). Thirty-eight-day-old plants.

These Dwarf Stone plants have stouter stems than those of Marglobe. This agrees with the observations of Houghtaling (1940), who found that the diameter of the primary body of a stem is determined at the stem apex where the new tissues are being formed.

CELL LENGTHS IN TOMATOES.—General trends.—The lengths of successive cells in the terminal meristematic regions of dwarf and tall tomatoes at four stages of development are shown in figures 8 to 11. It may be seen that the cells of the promeristem become shorter as the plant grows older. One might expect that as the cells at the apex decrease in length, those immediately behind this region would also be shorter than at preceding stages. This is the case for plants older than seven days, and as a plant grows older a much greater portion of the terminal part of the stem is occupied by cells which are shorter than comparable ones of younger plants.

A difference in the rate of division of comparable cells during the plant's ontogeny was suggested by the greater number of short cells in the apex of older plants as contrasted with the number in young plants. That is, where cell division proceeded most rapidly, the interval between divisions would be shorter and hence the cells would be smaller. Table 1

TABLE 1. Length of cell division zone in stem tips of Marglobe and Dwarf Stone tomatoes.

Age in days	Distance of last mitotic figure from apex (in microns)	
	Marglobe	Dwarf Stone
23	1,835	1,003
38	5,623	4,151

shows the extent of the region of cell division in stem tips of Marglobe and Dwarf Stone plants 23 and 38 days old. In both these varieties cell division extends over a region approximately 3,000 microns longer in plants 38 days old than in those 23 days old. Thus not only are the cells shorter in the apex of older plants, but, as a result of a longer zone of cell division, more cells are dividing.

Dormant embryos.—The first ten cells in the shoot apex of the two varieties were very uniform in length. However, cells 10 to 50 of Dwarf Stone plants, which lay in the unelongated hypocotyl of the embryo, were longer than comparable ones of Marglobe. The difference of the means of the two varieties was twelve times the standard error, the greater length of the Dwarf Stone cells being clearly significant and showing an inverse relationship between cell length and stem length.

Seven-day-old seedlings.—The promeristem cells of the two varieties were again equal in length. The cells behind the promeristem had elongated and formed part of the hypocotyl. However, Marglobe cells were now significantly longer than those of Dwarf Stone, a reversal from the condition observed in the dormant embryos. To accomplish this, Mar-

globe cells must have elongated more rapidly than those of Dwarf Stone. Some cell division must occur at the apex, however, for cells 1 to 35 were shorter than similar cells in the embryo. For Marglobe cells in the seedling to be longer than those of Dwarf Stone, their rate of elongation must have been faster during the period of germination, since presumably there was little division in the seedling.

Twenty-three-day-old plants.—At this stage of development comparable cells of Marglobe and Dwarf Stone plants were essentially equal in length up to the twentieth cell from the apex. All cells were clearly shorter than comparable ones of the preceding stage. Cells of Dwarf Stone at greater distances from the stem apex were slightly longer than those of Marglobe, but since the difference in their mean lengths was only about two times the standard error, the significance of this difference may be questioned.

Thirty-eight-day-old plants.—As in all preceding stages, the cells of the promeristems were of equal length for both forms. On the other hand, the tendency for older cells of Dwarf Stone individuals to be longer than those of Marglobe was even more pronounced. The difference in mean cell length for cells 40 to 115 was definitely significant, for it was ten times its standard error.

The cell lengths of these 38-day-old plants bear a definite relationship to plant height. The greater length of these Dwarf Stone cells indicates that cell division is going on less rapidly in the embryonic region of Dwarf Stone stem tips than in those of Marglobe. Not only are cell divisions in the dwarf plants less frequent, but they are also less numerous. There is a striking difference in the extent of the mitotic region of tall and dwarf plants which could be observed in this and in the preceding stage. In the seedlings mitotic figures were not readily observed, probably because growth of the hypocotyl results almost entirely from the elongation of cells which lie in the embryo, with only a limited amount of cell division at the apex. However, in the later stages, mitotic figures could be observed, and the approximate extent of the region of cell division could be determined (table 1). The mitotic zone of Dwarf Stone plants was always shorter than that of Marglobe, i.e., cell division is confined to a smaller portion of the stems. In plants 23 days old, mitoses were observed in a region more than 1,800 microns long in Marglobe plants, but only slightly above 1,000 microns in Dwarf Stone plants. In plants 38 days old, cell division figures were found in a region 5,500 to 5,600 microns long in Marglobe plants and 4,000 to 4,200 microns long in the dwarfs.

It is readily seen that at least in plants 23 and 38 days old there is a difference in the cell lengths in tall and dwarf forms which is a reflection of their respective rates of cell division. Furthermore, there is good evidence that the greater height of Marglobe plants is accounted for in large part by a longer region of embryonic cells in the stem tip, which, in contrast to the embryonic region of Dwarf Stone plants, gives rise to a greater number of cell generations. The difference then between tall and dwarf plants is estab-

lished in the growing points, since mature cell size is the same in both varieties.

CELL LENGTHS IN ZINNIAS.—General trends.—There is a remarkable similarity in the developmental pattern of cell lengths of zinnias and tomatoes. Successive cell lengths of each stage are shown in figures 12 to 15. Absolute cell size was not identical. The older cells of zinnia are generally longer than those of tomato, but the same trends were apparent. As in tomato, cells of the seedlings were longer than at any other stage. There was a slight decrease in length of the cells in the promeristem at each successive stage of development, but the trend was not as definite as in tomato. As the plants developed, the older cells, i.e., those farthest from the apex, were generally shorter than comparable ones at preceding stages, but the extent to which they were shorter was not as great as in tomato.

Embryos, seedlings, and plants 15 and 22 days old.—As in tall and dwarf tomatoes, cells 10 to 50 of nine-day-old seedlings of the Giant variety were longer than those of Lilliput, but these longer cells evidently do not establish a difference in height between the two forms. Comparable cells of the two varieties in the embryo were equal in length, in this respect differing from those of the tomato where the dwarf plants had the longer cells.

In zinnia, as in tomato, older cells of dwarf plants were longer than similar ones of tall plants. Commencing with the 45th cell from the apex of 15-day-old plants the Lilliput cells were significantly longer than Giant. This difference in cell length between Giant and Lilliput varieties was even more significant in 22-day-old plants. Because of the lack of visible mitoses in this material it was impossible to determine the extent of the region of cell division.

Although zinnias are not related to tomatoes in most respects, the similarity in the changes in cell lengths of their tall and dwarf varieties was outstanding. In both, the cell lengths in the promeristems decreased as the plants matured. Likewise cells of dwarf plants in the later stages were longer than those of tall plants. Further investigation is necessary to establish where there is a relationship between the lengths of cell division in regions in Giant and Lilliput zinnias which corresponds to that observed in Marglobe and Dwarf Stone tomatoes.

DISCUSSION.—Two aspects of the problem of cell length and its relation to plant height must have consideration here: (1) the changes of a general nature which occur during the vegetative ontogeny of tall and dwarf plants alike, and (2) the relationship of cell length to the problem of height differences which are hereditary.

General trends.—Cell lengths in the promeristems of zinnias and tomatoes, as has been noted, are progressively shorter as a plant grows older. This is contrary to the general conception that the cells in this region are equal in size at all stages of the plant's development. Whaley (1939) made a study of cell volume in promeristems of a series of tomatoes of vary-

Fig. 12-13. Successive cell lengths in the terminal meristematic regions of Giant and Lilliput zinnias.—Fig. 12 (above). Dormant embryo.—Fig. 13 (below). Nine-day-old seedlings.

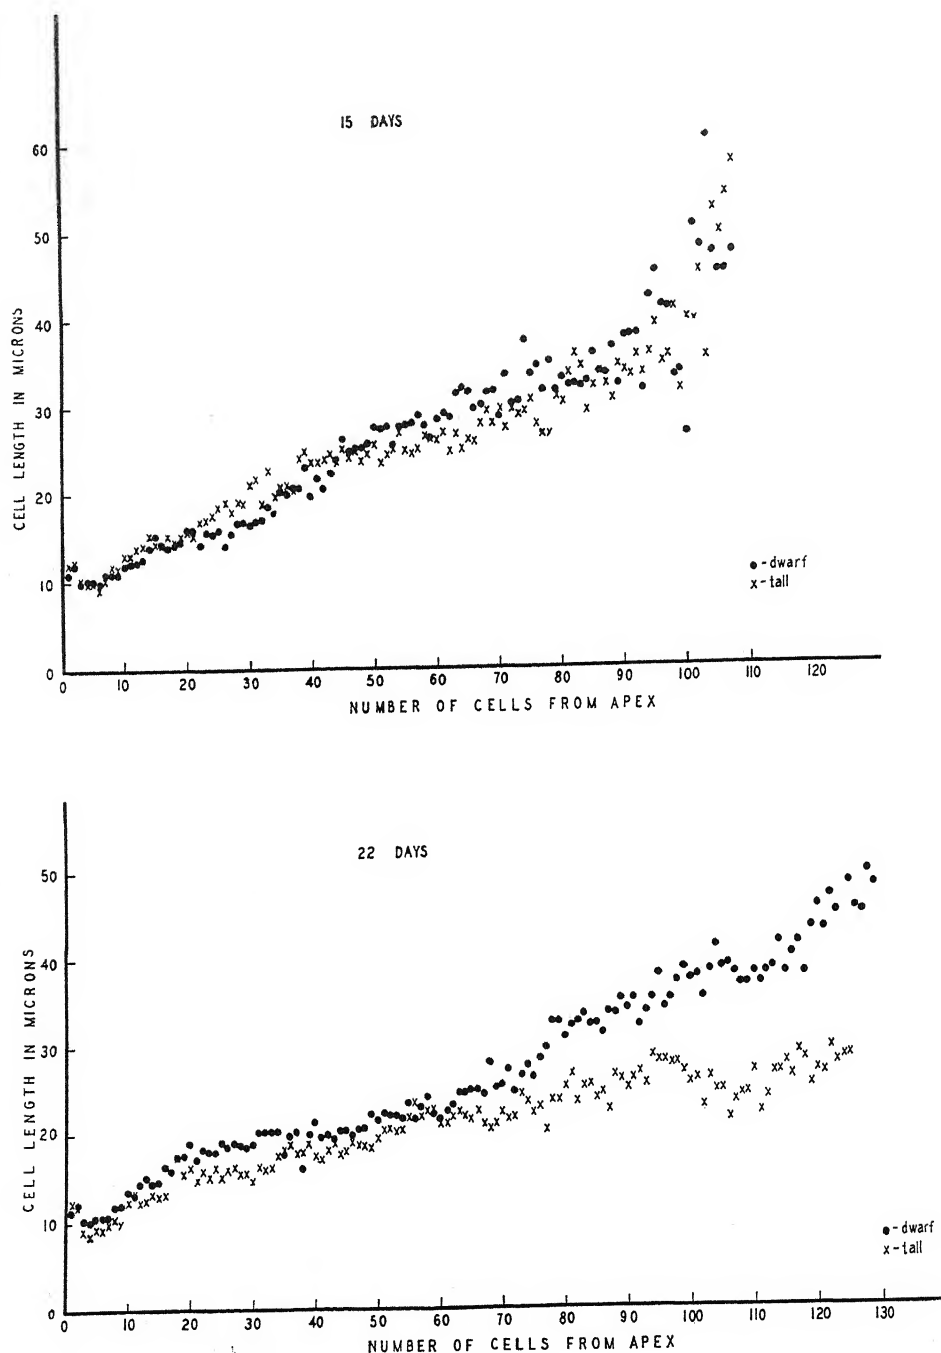

Fig. 14-15. Successive cell lengths in the terminal meristematic regions of Giant and Lilliput zinnias.—Fig. 14 (above). Fifteen-day-old plants.—Fig. 15 (below). Twenty-two-day-old plants.

ing ages and found that the volume of promeristem cells also decreased. He related this smaller volume of promeristem cells in older stem tips to a greater competition for food and food materials accompanying the increased size of the plant and the formation of more growth centers in which cell division was continually occurring.

The present investigation on cell size, in contrast to Whaley's, includes an analysis of cell lengths in the region of elongation and vacuolation as well as in the promeristem. As in the promeristem, cell lengths of both tomatoes and zinnias in this region also change as the plant matures, cells of one stage being regularly shorter than comparable cells of the

preceding stage. In these older plants the region of short cells extended farther down into the stem, and it was found that this was correlated with a longer embryonic region in the stem tips of older plants.

It is important to know that cell size in comparable regions is not the same for plants of different ages and phases of development. This fact has been overlooked prior to the relatively recent investigations in developmental analysis of cell and organ size relationships. Obviously where organ sizes are different, a study of comparative cell sizes should be based on materials of known age or state of maturation so that corrections may be made for normal changes in cell size. The problem of absolute cell size and its relation to organ size may not be as important as the relative size of cell to organ, and this can only be determined, as in the present study, by following cellular ontogeny. Furthermore, the lack of definition and consistency in the use of the term "cell size" has led to the present confusion concerning the relationship of cell size to organ size.

It is no longer possible to think that the chief center of cell division is in the relatively short zone 60 to 100 microns from the stem tip. Cells behind this region also divide although they are in various stages of vacuolation. Observations in the tomato stem tips showed many instances in which vacuolate cells 45 microns long were dividing. In fact, more mitotic figures were observed in vacuolate cells than in the regions of non-vacuolation at the apex. Lateral organs, such as leaves and axillary buds, are undoubtedly formed by cell division in the promeristem, but the activity of cells in this region is not solely responsible for stem length. Priestley (1929) was among the first to point out that vacuolate cells as well as non-vacuolate ones are capable of division in the stem apex.

Although the tomato and zinnia plants were quite different in size and appearance, the trends in the development of cell length in the stem apex are remarkably similar. Thus, although absolute cell size in these two genera is not identical, the behavior of the cells follows a very similar developmental pattern which operates throughout the whole period of growth.

Cell length and plant height.—There seems to be no consistent positive relationship between cell length and stem length. The cells of the promeristem are approximately equal in length in tall and dwarf forms. Comparable cells in the regions of elongation in tall and dwarf plants, however, show a definite sequence of shifting size relationships during development. It has already been seen that in the embryos of tall plants the cells were generally shorter than those of dwarf plants; that in the seedlings the situation was reversed, with cells of tall plants the longer; and that another shift occurred in the third developmental stage where cells of the dwarfs tended again to be longer. The general growth pattern appeared fairly well established and stable at that stage, for in the last stage prior to flowering, the greater length of cells in the dwarfs was even more pronounced. Thus,

it is obvious that the growth of cells in the shoot apex is a complicated process which is subject to modifications at various stages in the plant's ontogeny.

It has been shown that cell division is confined to a shorter region of the stem tip in Dwarf Stone individuals. This seems to account for the longer cells of dwarf plants 23 and 38 days old. Where cell division stops early and is followed by elongation, the cells will be longer than in individuals where cell division extends over a greater region and maturation and elongation are not allowed to go to completion. Thus, tallness in the Marglobe plants is probably due to a greater number of cell generations, since observations on mature cell size showed no differences in the cell lengths of tall and dwarf varieties.

Observations on the extent of cell division do not rule out the possibility that there may be different rates of cell elongation in Marglobe and Dwarf Stone varieties. For example, Anderson and Abbe (1933) have shown a definite case in which size of cell was determined by the rate of secondary wall formation which in turn limited cell elongation. No evidence was obtained on secondary wall formation or actual rate of elongation in the tomato varieties here studied.

Certain physiological processes such as rate of auxin production may differ in tall and dwarf plants. Since there is evidence that auxin is related to cell elongation and, therefore, presumably to plant growth, it may play an important rôle in determining tallness and dwarfness. Indeed, van Overbeek (1935, 1938) studied dwarfness in maize from a hormonal point of view and found that normal and *nana* forms produced equal amounts of auxin in the early stages, but that the dwarf variety *nana* destroyed it more rapidly.

In the present study, the use of the *Avena* method and diffusion technique in preliminary investigations on the hormone content of a number of tall and dwarf forms showed some indication that there was more growth substance in the tall varieties. This research has not been carried on because the diffusion method leaves much to be desired in quantitative determinations of growth hormone content. Research on the hormonal aspect of plant height awaits the development of suitable extraction techniques for particular green tissues.

In the zinnias the differences in height between Giant and Lilliput forms were not pronounced in the early stages. However, elongating cells were comparable in their behavior to those of tomatoes. Whatever may be the explanation for this lack of height difference (see paragraph 6, page 181), the significant fact seems to be the similarity in the developmental pattern and cellular organization at the shoot apex of "tall" and "dwarf" zinnias. One might expect, because there are no height differences between the zinnias used as material in this study, that their internal pattern of development would be identical. However, such is not the case, for by analogy with the tomato varieties, the internal development of the

embryonic tips of Giant and Lilliput plants is the same as though they had actually developed into tall and dwarf individuals. Thus there is a fundamental difference in the embryonic tissues of Giant and Lilliput stem tips, but this difference was not translated into actual height differences under the existing environmental conditions.

Sinnott (1940) has observed that in small and large fruited cucurbits there is also a fundamental developmental pattern which proceeds regularly regardless of the manner in which the substance of the organism is divided up. In the zinnias studied the factors responsible for inhibiting their potential development must be those which act on the differentiation and maturation processes of cellular ontogeny, since in their early cellular ontogeny both tall and dwarf plants are similar.

In viewing the organism as a whole one may conclude from this investigation that there is a basic histological pattern of development, fundamental in organization, and modified in various ways in response to genetic changes. While the problem of the relationship of mature cell size to mature organ size is an important one in the study of size differences, it merely represents the end product of a whole series of changes. Only a greater knowledge of the processes of development and differentiation and the changes which occur in the ontogeny of both cells and organs will make it possible to interpret the organism as a whole in terms of its parts.

SUMMARY

A developmental study was made of cell lengths in the apical meristematic regions of genetically tall and dwarf races of *Lycopersicon esculentum* and *Zinnia elegans* during their early growth and development. The tall and dwarf plants in each case were grown from seeds of essentially equal weight. Measurements of series of successive cells were made (in embryos, seedlings, and older plants), extending from the apex in a proximal direction, to determine

whether there was a relationship between cell length in meristematic regions and mature stem length.

In the embryo and at all later stages of development, Marglobe tomatoes were always taller than Dwarf Stone. The Giant zinnias were not appreciably taller than Lilliput until flower formation.

No difference in meristem size was apparent between tall and dwarf plants.

Cell lengths of the first ten cells in the series, forming the promeristem, decreased as the plants grew older. These cells were equally long for tall and dwarf varieties, thus showing no correlation with plant height.

Cells were elongating directly behind the promeristem of both zinnias and tomatoes, but their lengths at successive stages in the plant's ontogeny were less as the plant matured. These shorter, vacuolate cells in the older stages of Marglobe tomato plants were associated with a longer meristematic region, thus accounting for the greater height of these plants by making a greater number of cell generations possible. In contrast, embryonic cells of Dwarf Stone are longer because they attained maturity sooner, and thus stopped dividing.

There was a series of shifting size relationships of the vacuolate cells in tall and dwarf plants, indicating that tallness and dwarfness are not due to absolute differences in lengths of cells at the apex.

Although there were no sharp differences in total height of Giant and Lilliput zinnias, the behavior of the cells in their respective meristems was essentially the same as that of tall and dwarf tomatoes. Thus, while there is no constant relationship of cell length to stem length during vegetative ontogeny, there is, nevertheless, a fundamental and genetically controlled sequence of changing size relations in the terminal meristems which is ultimately related to differences in cell number and thus to differences in plant height.

HEREDITARY SUSCEPTIBILITY TO X-RAY INJURY IN TRITICUM MONOCOCCUM¹

Luther Smith

EXTENT AND NATURE OF INJURY.—In the fall of 1939 dormant seeds of three stocks of einkorn were X-rayed simultaneously for a study of mutation rate. One was much more severely injured by the treatment (7,500 r-units) than the other two. The greater susceptibility of this stock to X-ray injury has since been confirmed in comparisons with various other stocks and has been shown to be conditioned by a gene. This factor has been called "X-ray susceptible" or "susceptible" (symbol *xs*). Following treatment of dormant seeds the injury takes the form of more pronounced flecking on the first leaves, slower growth, and death from smaller doses than are required to kill normal seeds.

In one test, treatments of 4,000 r, 8,000 r, and 12,000 r-units were applied to dormant seeds (thirty seeds per group) of the susceptible and of a non-susceptible stock. After ten days, seedlings from the susceptible line rayed 8,000 r were about half as tall as those given 4,000 r. None grew from the seeds given 12,000 r. In the resistant line there was only a slight difference between the 4,000 r and 8,000 r groups, while the 12,000 r group was about half as tall as the 4,000 r group. In another trial an early-maturing line and the susceptible stock were compared. Treatments of 5,000 r, 10,000 r, and 20,000 r were applied. Sixty seeds were given each treatment and divided into two series, thirty seeds per treatment. After they were rayed, the seeds were soaked in tap water at about 22°C. for twenty-four hours and then planted in soil flats together with untreated checks. From figure 1 it is apparent that the early-maturing stock grew somewhat more rapidly than the susceptible (legend for fig. 1). This was due in part to better seed, but some of the difference was due to the earliness characteristic. Neither stock was distinctly injured by the 5,000 r treatment, and the early was reduced in height only slightly by 10,000 r while the susceptible line was severely damaged. The

normal (early) line was reduced in height by 20,000 r to about the same degree that the susceptible line was by 10,000 r, while only a few coleoptiles emerged from the susceptible line given 20,000 r. The two series were practically identical. The data on emergence and height of plants are presented in table 1.

A A' B B' C C' D D'

Fig. 1. Ten-day-old seedlings of an early (normal) stock and an "X-ray susceptible" stock of einkorn. A (normal), A' (susceptible), no treatment; B, B', 5,000 r; C, C', 10,000 r; D, D', 20,000 r. Note the serious injury to the "susceptible" line given 10,000 r though the normal line given the same dose shows little, if any, injury. See text.

The two series were combined in obtaining the values. Thus each percentage represents sixty treated seeds. A number of other trials were made, and each demonstrated clearly the greater injury to the susceptible line.

INHERITANCE OF SUSCEPTIBILITY.—The susceptibility has been demonstrated in three generations. It apparently is recessive, as 138 seeds of the constitution *xs xs* × ++; 118 ++ × *xs xs*; and 116 ++ × ++ produced seedlings which were indistinguishable following treatments of 8,000 r or 10,000 r, though they were clearly less injured than the homozygous susceptible given the same treatments.

Further evidence that susceptibility is recessive and evidence that only one gene is concerned was obtained by X-raying seed from F₁ plants. The ratio of relatively uninjured to severely injured seedlings was approximately 3:1.

TABLE 1. Comparison of the effects of X-rays on emergence and height of seedlings from a normal and an X-ray susceptible line of einkorn.

Treatment	Seeds producing seedlings		Average height in terms of the untreated check	
	Normal	Susceptible	Normal	Susceptible
	%	%	%	%
Check	100	100	100	100
5,000 r	104	94	103	92
10,000 r	100	84	94	42
20,000 r	88	16	32	4

TABLE 2. *A comparison of the induced mutation rate of a normal and the "susceptible" stock. (Not adjusted for size of head progeny.)*

Stock	Treatment	Head progenies	Seedlings per progeny	Mutants	Heads with mutants
		No.	No.	No.	%
Normal	5,000 r	523	16.6	17	3.3
Susceptible	5,000 r	466	11.6	13	2.8

Additional evidence on both of these points was obtained from treating seed from twenty-four F_2 plants (fifty seeds from each plant). As would be expected, the classification of the F_2 plants into homozygous and heterozygous susceptible and non-susceptible was in some instances uncertain, but the differences among their progenies were distinct, and the classification fitted reasonably well the postulated 1 homozygous non-susceptible : 2 heterozygous susceptible : 1 homozygous susceptible. Five plants were classified as $Xs Xs$, thirteen as $Xs xs$, and six as $xs xs$. These populations also supplemented the F_2 data in indicating that some plants gave progeny in the ratio of 3 normal : 1 susceptible.

TESTS FOR LINKAGE OF SUSCEPTIBILITY FACTOR.—The factor for susceptibility was first found in a "glume-awned" (Smith, 1939) mutant stock. However, some glume-awned plants seem not to be "susceptible"; hence, the two characters are not two effects of the same gene. Also in F_2 and F_3 populations seedlings which were homozygous for a recessive mutant gene, js , very closely linked in repulsion with the glume-awned factor (ga) which came into the cross with xs , were "susceptible." In another population segregating xs and $gl-2$ (Smith, 1939), known to be unlinked with ga , the $gl-2 gl-2$ seedlings were susceptible. Thus xs appears not to be linked with either of these unlinked genes, and further tests are necessary to find a linkage for it.

EFFECT ON MUTATION RATE.—As xs has an effect on the susceptibility of seeds to X-ray injury, and as it is known that X-rays have distinctly different effects on the mutation rates of organisms (Stadler, 1931) and that genes may alter mutation rates (Demerec, 1937), it was thought possible that the susceptibility to injury might be associated with an in-

creased mutation rate. However, in preliminary tests there was no appreciable effect of the gene on mutation frequency.

Dormant seeds of the susceptible and a normal stock simultaneously were given a treatment of 5,000 r units and planted immediately. Head progenies of the resulting plants were grown to the seedling stage. About 2.8 per cent of the head progenies of the susceptible line were segregating for a conspicuous mutant (white, yellow, virescent, etc.) while 3.3 per cent of the head progenies of the normal line contained mutants (table 2). However, the normal line averaged 16.6 seedlings per head progeny as compared to 11.6 for heads of the susceptible line. Additional data from segregating susceptible and other normal stocks also indicated that there were probably no significant differences in mutation rates (table 3), though two of five segregating stocks (e and h) had a higher frequency of mutations.

X-RAY SUSCEPTIBILITY FACTOR AND HEAT TOLERANCE.—Some investigators (e.g., Shkvarnikov and Navashin, 1935) have likened X-rays to heat in the production of effects in living organisms. Therefore, the effect of heat on the X-ray susceptible and other stocks was compared. The "susceptible" stock was not especially susceptible to heat injury. Rather the reverse was true. In one series of treatments comparing the effect of high temperatures on the viability of dormant seeds of six stocks of einkorn (fifty seeds per treatment), the "susceptible" line was equal in viability to the best of the stocks at 50°C. and 60°C. for five and ten days. It was the only stock which germinated at all after five days at 70°C. In this comparison the seeds were germinated immediately after removal from the ovens. In another series in which the seeds were allowed a day between treat-

TABLE 3. *A comparison of the induced mutation rate of several normal and several segregating "susceptible" stocks. (Not adjusted for differences in size of head progeny or dose.)*

ment and germination, the "susceptible" line was not outstanding in viability.

DISCUSSION.—As Sax and Swanson (1941) point out, sensitivity to X-rays has been of two sorts: (1) The physiological or killing effect and (2) the genetic effect. The factor here reported in einkorn apparently affects only the physiological sensitivity. Hence, the discussion will be limited to a small part of the literature dealing with physiological sensitivity and the factors which modify it. Certainly some of the factors could not be operating in the material reported here but are mentioned in order to indicate the types of things which affect sensitivity.

Physiological sensitivity to X-rays varies greatly among species and genera and even within species. Johnson (1936a, b) studied the sensitivity of 100 species distributed among fifty families. Of seventy species which were compared directly, fifteen were unaffected, fifteen were slightly affected, and forty were noticeably affected by X-rays under the conditions imposed. She also found (1933) differences in the sensitivity of three varieties of *Atriplex hortensis*. A red and white were more severely injured than a green variety. Mavor (1927) reported that female pupae of *Drosophila melanogaster* were more resistant to X-rays than male. Stadler (1929) observed differences in survival of seeds of several species of wheat and oats following X-ray treatments. The polyploid species were more resistant to injury than the diploid.

It is well established that the conditions of treatment or state of the individual or tissue has an effect on the tolerance for X-rays. Stadler (1931) reported that dormant barley seeds tolerated a dose fifteen to twenty times as great as germinating seeds. Soaked seeds were more sensitive than dry, dormant seeds.

Johnson (1926) reported that catalase activity was decreased by x-irradiation while oxidase activity was unaffected in *Helianthus annuus*. She (1933) determined that the greater susceptibility of a red and

a white variety of *Atriplex hortensis* as compared to the green (above) was paralleled by a greater decrease of catalase activity in the former. Cattell (1931) reported that vitamin B in wheat embryos was destroyed by heavy doses of X-rays. Skoog (1935) observed that X-irradiation inactivated auxin.

The mechanism by which the factor herein reported increases the susceptibility to X-ray injury (though apparently not affecting mutation rate or susceptibility to heat injury) has not been determined. It is not due to higher water content. Seeds of the early (normal) line and the susceptible line (fig. 1) had 11.7 per cent and 11.5 per cent moisture respectively. Also the meiotic chromosomes of the susceptible line appeared to be the same size as those of normal stocks. It is hoped the susceptibility can be analyzed as a controllable alteration in the chemical constitution or hormone or vitamin relations.

The factor here discovered may have some bearing on the difficulty encountered by investigators in duplicating the results of others involving studies of X-ray tolerance. These difficulties heretofore have frequently been attributed to differences in apparatus rather than to differences in the genetic or physiological constitution of the organism.

SUMMARY

A mendelian factor was found in einkorn wheat (*Triticum monococcum*) which distinctly increased the susceptibility of dormant seeds to X-ray injury. In preliminary tests the factor had no apparent effect on mutation rate nor on susceptibility to heat injury.

Arlo I. Smith

IT HAS been determined that adventitious roots in stem cuttings may arise in many different tissues of the stem, nearly always in association with cells near the conducting tissues. This condition also maintains in *Tropaeolum majus* L. This paper has been prepared because it was noted that adventitious roots arise from stem cuttings of the garden nasturtium in a somewhat shorter time than is required in many other herbaceous plants. With no chemical treatment roots emerge from stem cuttings in five to seven days.

Since little has been added to the literature during the past year, attention is called to Swingle's (1940) rather exhaustive review concerning various phases of regeneration and vegetative propagation.

MATERIALS AND METHODS.—Cuttings were made from stems of various ages and placed in slightly alkaline tap water. In about five days roots began to emerge from the basal 2 to 3 mm. of the stem cutting. Somewhat later, roots appeared farther up the stem, mostly at the nodes. In most cases the roots emerged at right angles to the stem axis. Material was taken from the basal 2 mm. of the cuttings, fixed in formalin-acetic acid-alcohol and imbedded in paraffin. Sections were made at thicknesses varying from 5 to 20 microns, those at 15 microns proving most satisfactory. Staining was done with safranin and fast green. Photomicrographs were taken with a Leica copying attachment upon Eastman Bibliophile film. No filters were used.

The Salkowski indol test, as commonly used by bacteriologists, was used on freshly harvested *Tropaeolum* plants without any indication that indol is produced naturally. It was thought that such production may account for the rapid root formation.

STEM ANATOMY.—In *Tropaeolum majus* L. the single-layered epidermis has sparsely scattered stomata (fig. 2) and rather small substomatal chambers. The cortex consists of six to eight layers of cells between a distinct endodermis and the epidermis (fig. 1). Probably due to sectioning, the endodermal cells were found to have collapsed in a few cases (fig. 3, 4). Although some starch grains are present in the

cortex, they are not as abundant here as in the outer areas of the pith (fig. 1, 2). These starch grains disappear after the cuttings have remained in the water for two or three days (fig. 3, 4). The pericycle is a rather poorly defined tissue (fig. 1, 3) adjacent to the definite endodermis with Casparian strips (fig. 1, 2).

Vascular bundles are separated by medullary rays in young stems, but the interfascicular cambium of the older stems makes complete cylinders of conducting tissue. Small vascular bundles are frequently found between the larger ones (fig. 2, 3).

The pith of the stem is quite large and, as mentioned above, is abundantly supplied with starch grains (fig. 1, 2).

ADVENTITIOUS ROOTS.—Adventitious roots make their appearance comparatively early, although there is no evidence of preformed root primordia. Cuttings that had been in water three to four days were best suited to the study of root initials (fig. 3, 4).

Roots are always found to appear in the interfascicular region between the endodermis and the interfascicular cambium when the latter is present (fig. 2, 3). At first it is difficult to distinguish between a very small vascular bundle and a root primordium (fig. 3). In the root primordium the nuclei are larger, the protoplasm more dense, and the cells larger than in the phloem of the vascular bundle. Both have a similar location in the stem cuttings (fig. 3).

The youngest root primordia are distinguishable before any meristematic activity of the pericycle is noted. These primordia are located in the ray parenchyma cells between the pericycle and the interfascicular cambium when the latter is present (fig. 3, 4). Since these parenchyma cells normally give rise to interfascicular cambium, they possess meristematic potentialities.

As meristematic activity continues, the cells between the root primordium and the endodermis enlarge and also become meristematic. These cells which undoubtedly are pericyclic become part of the root and lose their identity as pericycle (fig. 5). Cells of the endodermis enlarge greatly as the root increases in size (fig. 5, 6), but these cells do not undergo mitoses. Shortly after the endodermal cells enlarge, a pocket appears in the cortex ahead of the young root (fig. 6). The endodermis thereafter soon

¹ Received for publication August 18, 1941.

Root primordium similar to figure 3.—Fig. 5. Young root from four-day cutting showing enlarged endodermis (EN) of the stem. Compare with figure 6.—Fig. 6. Similar to figure 5 but plerome (PL) becoming more definite. Pocket has appeared outside of endodermis (EN).—Fig. 7. Similar to figure 6; endodermis and several cortical cells have collapsed.—Fig. 8. Histogens have definitely appeared in both roots that arose side-by-side.

disintegrates. No feasible chemical test was devised to ascertain whether the endodermis secretes a cellulose digesting enzyme which may aid the root in its emergence. Similar conditions were observed in *Begonia* cuttings (Smith, 1936), but Priestley and Swingle (1929) and later Swingle (1940) seem to doubt the possibility of adventitious roots being able to emerge by any fashion other than mechanical pressure. In *Tropaeolum* and *Begonia* it seems that both mechanical pressure and digestion work together in root emergence, thus accounting for such pocket formation in the earlier stages.

Root histogens appear before the root has emerged from the cortex, the plerome being the first to appear (fig. 6, 7, 8). The periblem is distinguished, and the root cap is in evidence before emergence (fig. 8). Nuclear divisions of the pericycle at the periphery of the primordium indicate that this tissue may have something to do with periblem and root cap formation while the initial cells give rise to the plerome.

SUMMARY

Adventitious roots in stem cuttings of *Tropaeolum majus* L. originate in the ray parenchyma between a

poorly defined pericyclic region and the interfascicular cambium when such is present. The pericycle later adds to the root initial. The endodermis ahead of the root primordium enlarges but does not undergo mitoses. A pocket appears ahead of the young root, outside the endodermis, indicating that cellulose digestion probably takes place, thus aiding root emergence. Histogen differentiation occurs before the root emerges from the stem.

DRAWING GUIDE FOR ZINC ETCHINGS

Letters, lines, and dots in relation to reduction for the printed page. Top—Reduction to 1/4. Middle—Reduction to 1/2. Bottom—Original size.

Reprinted by permission of the authors from: RIKER, A. J., and REGINA S. RIKER. 1936. *Introduction to research on plant diseases*. 117 p. Published by the Authors, Department of Plant Pathology, University of Wisconsin, Madison, Wis.

Note that thin black lines hold up fairly well in reduction, but that small black dots and small white spaces between black lines or dots may be lost. If placed too close together, dots and lines produce black blotches when the drawing is reduced. Keep the shading rather open. The degree of reduction needs to be known before the drawing is inked in.

Delicate shading may be obtained if the size and spacing of the dots are adjusted to the degree to which the drawing is to be reduced.

A DEVELOPMENTAL ANALYSIS OF INHERITED LEAF PATTERNS IN *TROPAEOLUM*¹

W. G. Whaley and C. Y. Whaley

MUCH ATTENTION has been directed of late to study of the mechanisms by which genes control the development of specific patterns. Leaves of certain plants, in which growth is essentially two-dimensional, present admirable material for such studies. Hammond (1941) has recently made an extensive investigation of the genic control of leaf shape in *Gossypium*. Developmental changes in the form of the leaves of *Tropaeolum majus* L. have been studied in considerable detail by Smirnov and Zhelochovtsev (1931) and by von Papen (1935). The genetic background of certain of the many leaf shapes of the genus *Tropaeolum* has been determined by the writ-

but are characterized by five lobes as seen in figure 3. As has been reported previously (Whaley, 1939) the hybrid from a cross between these two species bears leaves which are the same shape as those of *T. majus* but are larger than those of either parent. The F₂ from this cross was found to contain, in addition to plants with leaves similar in shape to those of each parent, plants bearing a third type of leaf. This new leaf is considerably smaller at maturity than either of the other types and is sharply or acutely lobed (fig. 2). Genetical analysis of this and other crosses has indicated that leaf shape here is determined mainly by two genes in epistatic rela-

Fig. 1-4.—Fig. 1. Juvenile leaf.—Fig. 2. Acutely lobed leaf, *lu*.—Fig. 3. Roundly lobed leaf, *lU*.—Fig. 4. Orbicular leaf, *LU* or *Lu*.

ers and was reported in an earlier paper (Whaley, 1939). The data reported here are the result of an attempt to study intensively the ontogenetic form changes of leaf types whose genetic background is known, and to correlate the findings in such a manner as to obtain some idea of how the genes concerned operate in the development of shape differences.

MATERIALS AND METHODS.—*Tropaeolum majus* L. var. Golden Gleam bears leaves which are broadly orbicular in outline and which are relatively large when compared with the leaves of other species of *Tropaeolum* (fig. 4).

T. peltophorum var. *fimbriatum*² has leaves which are of the same basic shape as those of *T. majus*

¹ Received for publication September 8, 1941.

The authors wish to express their appreciation to the Massachusetts State College for financial assistance which made this study possible.

² *T. peltophorum* var. *fimbriatum* is also known as *T. Lobbianum fimbriatum*. Neither name has taxonomic validity. The former name is being maintained simply because the authors have used it in previous papers. The plant is of obscure hybrid origin, but it is homozygous for all the factors studied.

tionship. These genes have been designated as *L-l* and *U-u*. *L* produces orbicular leaves (fig. 4), and *U* in the absence of *L* produces roundly lobed leaves (fig. 3). Individuals which have the genetic constitution *lu* have acutely lobed leaves (fig. 2). Thus *LU* and *Lu* individuals have orbicular, *lU* roundly lobed, and *lu* acutely lobed leaves.

It was noted early in the course of the investigation that the juvenile leaves of all of these types are identical in appearance. Shape can be determined accurately when the leaves are between 1 mm. and 2 mm. in length, and at this stage all the types are similar (fig. 1). These juvenile leaves are very acutely lobed and are somewhat longer than wide.

Five plants of each of the three leaf types were selected for the experiment. On each of the fifteen plants selected the youngest unfolded leaf was measured in the following manner. The point of petiole attachment was taken as a base and the distance from it to the tip of the leaf was recorded as distance B, to the base of the next adjacent sinus, G, the tip of the next lobe, F, etc., as shown in figure 5. The lines

Fig. 5. Diagram showing measurements made on each leaf. See text for explanation.

B, F, E, and D correspond to the principal veins of the leaf, while lines G, H, J, and C indicate the points of greatest indentation of the sinuses, except where during the later stages of development these points disappeared. The measurements were then taken along a line approximately halfway between each successive pair of veins. A complete set of measurements was made daily on each leaf. As soon as the next youngest leaf on each plant had opened enough, measurements of it were begun, and in a similar manner five successive leaves on each plant were measured. Thus, daily measurements from the 1 to 2 mm. stage to maturity were made on twenty-five leaves of each type. The plants on which the measurements were made were grown under uniform field conditions and all measurements taken during the same period of the growth cycle. In the few instances where any evidence of injury to leaves by handling or insects appeared, the measurements were immediately discarded and the next uninjured leaf was measured.

HETEROGONIC GROWTH.—Using the growth along the midrib from the point of petiole attachment to the tip of the leaf as a common base, growth along each line was compared with it. The comparison was made by plotting upon logarithmic paper growth along line B on the abscissae against growth along each of the other lines in turn on the ordinates. In making the curves, the successive points for an individual leaf were first plotted out. Then measurements for the four other leaves on the plant were plotted on the same sheet. Finally the measurements from five leaves on each of four additional plants of the same genotype were superimposed on the same grid. Each graph line thus represents the average of twenty-five leaves. On the graphs the leaf types are

numbered as follows: 1—acutely lobed, 2—roundly lobed, 3—orbicular. The figures following the graph line numbers are k values (Huxley, 1932) indicating the ratio of the growth rates.

Thus in figure 6, line 1 represents growth along the line from the point of petiole attachment to the point of greatest indentation of the sinus, G, compared with growth along the main vein of the leaf from the petiole attachment to the tip of the leaf in an acutely lobed leaf. The k value of 1.01 indicates that growth along these two lines is proceeding at approximately the same rate. The slope of line 3 in this same figure ($k=1.30$) shows that in the orbicular leaves growth along G is much more rapid than growth along B. The figure indicates, then, that in leaf type 1, the acutely lobed leaf, growth in the terminal lobe is at about the same rate as growth in the adjacent sinus area, but that in the roundly lobed leaf growth, during the period measured, proceeded more rapidly in the sinus area than in the lobe ($k=1.14$), and in the orbicular leaf growth is still more rapid in the sinus than in the lobe ($k=1.30$). Figure 7 shows that in all three types of leaves the terminal lobe and the next adjacent lobe, F, grow at about the same rate. Figure 8 represents growth of the second sinus, H, plotted against growth of the terminal lobe and indicates that relatively this sinus grows at about the same rate as G. Figures 9, 10, 11, and 12 show the growth of the other lobes and sinuses plotted in this same manner.

Next, the angles between the veins of the various leaves were measured and found to be constant, at least in the proximal parts of the veins. Not only were the angles constant, but approximately the same angles were found in all the leaf types. This fact made possible construction of growth diagrams based upon the relative growth constants as determined in figures 6 to 12.

These growth diagrams were made by projecting, at the proper angles, from a midpoint corresponding to the point of petiole attachment, lines representing the veins and deepest point of indentation of the sinuses. Then taking a given value for B from the growth curves, the length of each of the other projection lines at the time B equalled the given value was marked. Connecting lines were drawn between these points.

Figures 13, 14, and 15 show these diagrams for the three principal leaf types. Each diagram represents, by virtue of the method used, the average form of twenty-five leaves of a given genotype at various stages. It is readily apparent that they give a true picture of shape changes of each type, but two facts must be kept in mind when they are compared with figures 2, 3, and 4. First, the drawings for figures 2, 3, and 4 were made from leaves selected early in the experiment as typical of each genotype; and second, there are most certainly small growth differences, particularly around the margins and at the bases of the leaves within each type, some doubtless due to genes other than the two with which we are primarily concerned, and some perhaps environmental.

Fig. 6-11. Growth of the lobes and sinuses plotted against growth along the midrib. Plotted on double logarithmic paper.—Fig. 6. Growth of sinus G (fig. 5) against midrib B. 1, acutely lobed leaf; 2, roundly lobed leaf; 3, orbicular leaf.—Fig. 7. Lobe F against B.—Fig. 8. Sinus H against B.—Fig. 9. Lobe E against B.—Fig. 10. Sinus J against B.—Fig. 11. Lobe D against B.

Fig. 12. Growth of the lobes and sinuses plotted against growth along the midrib. Plotted on double logarithmic paper. Base C against B.

Considering first the smallest outlines in each of the diagrams (fig. 13, 14, and 15), which depict the shape of the leaves when line B is equal to 2.5 mm., it will be seen that all three leaves are identical in shape. Progressing toward the margin of the leaf, the next outline shows the shape at a length of 5.0 mm. (line B). At this stage the two lobed leaves are still very similar, but the sinuses of the orbicular leaf have begun to be obliterated by the more rapid extension of tissue, particularly along line G. At the next stage (B 10 mm.) the sinuses are still less apparent in the orbicular leaves, and their depth is perceptibly less in the roundly-lobed type. In the fourth outline (B 20 mm.) the sinuses have completely disappeared in the orbicular leaf, are still more shal-

low in the roundly lobed leaf, but remain relatively the same as earlier in the acutely lobed form.

The acutely lobed leaves mature, and growth ceases when B is approximately 25 mm. long, and their shape is, except for some minor adjustments, about the same as that of the juvenile leaf. The roundly lobed leaf grows somewhat longer, until B is 30 mm. in length. As seen in figures 6, 8, and 10, the sinuses here are growing about 1.15 times as rapidly as the lobes and the result is a partial obliteration of the lobes. What was originally selected as the orbicular leaf type is now known to have included plants of two different genotypes (*Lu* and *LU*) in which the relative rates of growth are approximately the same during the greater part of development, but which ultimately bear leaves of slightly different shape. Unfortunately, these types were not segregated in the original measurements. However, the evidence is sufficiently clear as to leave no doubt concerning the conclusions.

In the first of these (*Lu*), growth ceases when line B is approximately 35 mm. in length (the dotted line in fig. 15). At this point the sinuses, by their considerably more rapid growth, have just about overtaken the lobes, and the leaf is almost circular in outline. In the other type growth continues longer, usually until B equals 40 mm. or more. By the time this stage is reached the tissue of the sinuses, particularly G and H, has been extended considerably beyond the margins of the lobes. When this happens, the margins of the leaves either curl up in these areas or the whole periphery becomes wavy. In no case does the area which once was sinus project as a lobe, appar-

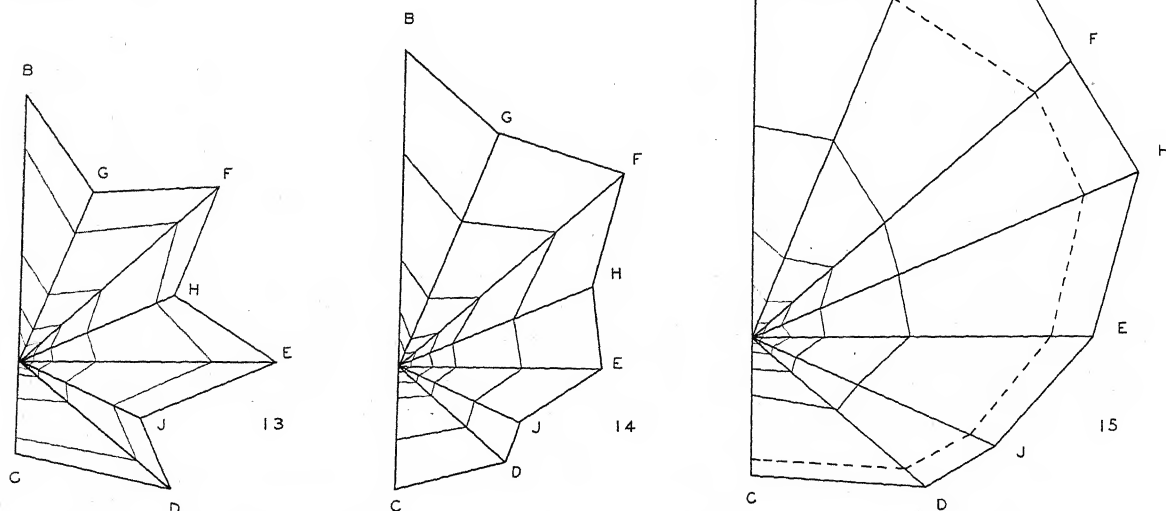

Fig. 13-15. Diagrams of progressive growth stages. See text for explanation.—Fig. 13. Acutely lobed leaf *lu*.—Fig. 14. Roundly lobed leaf *lU*.—Fig. 15. Orbicular leaf *Lu* and *LU*.

ently because of a lack of rigidity resulting from the absence of large veins.

It is also worthy of note that in all the leaves growth along line E is more rapid than growth in the terminal lobe. This, of course, makes the mature leaves wider with respect to length than the young leaves. Relatively, too, there is much stronger growth in the basal part of the lobed leaves, particularly in the acute one. While these facts are not so important in determining final shapes, they may be of value in any attempt to explain the mechanism.

Developmentally there appear to be, then, two major considerations involved in the determination of leaf patterns here. First, there are differences in the relative rates of growth of lobes and sinuses. In the acutely lobed leaf, which is known to be of the genetic constitution *lu*, the lobes and sinuses grow at about the same rate and the original juvenile pattern is maintained. In the roundly lobed leaves, *lU*, the sinuses grow somewhat faster than the lobes and thus tend to lose their identity. In the orbicular leaves, *LU* and *LU*, the sinuses grow very much more rapidly than the lobes. Secondly, there is a difference in the absolute size of the leaves at maturity (table 1). The acutely lobed leaves are smallest, the

TABLE 1. Measurements of mature *Tropaeolum* leaves (from Whaley, 1939).

Genotype	Leaf size, average of 100 leaves	
	Length (cm.)	Width (cm.)
<i>LU</i>	7.49±.09 ^a	8.32±.15
<i>Lu</i>	6.69±.09	7.29±.11
<i>lU</i>	5.59±.07	5.25±.06
<i>lu</i>	4.27±.12	4.63±.10

^a Standard error.

roundly lobed ones somewhat larger, and the orbicular ones of two sizes depending on their genotype, *LU* being larger. Obviously these two factors are correlated, for the leaf with the genetic constitution *LU* not only has more rapidly growing sinus tissue, but is larger, absolutely, than those leaves which are genetically *lu*. Likewise, leaves which are *Lu* not only grow larger, but their sinus tissue grows even more rapidly than that of the *lU* leaves. The presence of *L* and *U* together in the same plant does not, on the other hand, appear to affect the sinus/lobe growth any further, but does seem to produce greater absolute growth.

The leaf primordium in *Tropaeolum* arises from the apical meristem as a simple protuberance. This first outgrowth is the portion which is later to comprise the terminal lobe. It is flanked as growth proceeds by successive pairs of protuberances which eventually form the other lobes of the leaf. As Smirnov and Zhelochovtsev (1931) have shown, the very young leaf contains sharp deep sinuses. In all species whose leaves resemble those of *T. majus* the origin of the leaves appears to be similar, and the juvenile leaves are of the same general form.

Shape differences here, as the foregoing evidence attests, are due to differences in relative dimensional growth rates which appear fairly late in development. They are of the same general type as those found by Sinnott and Kaiser (1934) in the developing fruits of *Capsicum* as opposed to those which the same authors found in *Cucurbita* where the various shapes are visible in the earliest primordia and persist unchanged until the fruit matures.

In this instance, however, a further analysis has made it possible to obtain some idea of the manner in which these shape differentiations operate. Von Papen (1935) studying the growth of the leaf blade in *Tropaeolum* made a series of determinations of the number of epidermal cells per unit area of surface in different parts of the leaf at various stages of development. She found that in mature leaves there is a fairly even distribution, indicating that all the epidermal cells are of approximately the same size. Making counts on younger leaves, she determined that the number of cells was proportionately very much greater (i.e., the cells were smaller) in certain areas than in others and that the amount of difference varies inversely with the age of the leaf. The regions where, in the youngest leaves, the cells are very markedly smaller than elsewhere, are precisely the regions where the present authors found greatest relative growth to take place in the roundly lobed and orbicular leaves, namely, regions G, H, E, and the basal part of the leaf.

It is significant that von Papen's counts were made upon the young leaf of a plant whose mature leaves were almost orbicular. The authors have since made several counts upon juvenile leaves of the acutely lobed type and find that, provided the areas immediately adjacent to the veins are avoided, there is no significant difference between the size of the epidermal cells at the bases of the sinuses and elsewhere in the leaf.

A series of cell measurements was made on ten mature leaves of each type, taking a hundred cells from the area between lines B and G at a point approximately 20 mm. from the petiole in each instance. The results are given in table 2. Cell size measurements in leaves, particularly leaves of the larger forms where the tissue organization is very loose, are not particularly satisfactory, and, as can be seen in table 2, the differences obtained here are not all significant. They do, however, indicate that in comparable regions the larger leaves have considerably larger cells.

The details of cell size, then, resolve themselves along two definite lines. First, in those leaves which are later to become roundly lobed or orbicular the cells in the areas of greatest potential growth (epidermal cells at least) are relatively small. Second, there are different absolute levels of mature cell size in the different types, the largest leaves having the largest cells.

The individual action of the genes is not altogether clear, but the data seem to suggest that *U* produces a greater intensity of division in certain areas of the

TABLE 2. Cell size measurements in microns.

^a Standard error.

leaf very early during development. It appears also to increase the absolute mature size of the cells. *L* also has the effect of producing areas of smaller cells, cells with greater expansion potencies, but at the same time it produces considerably more cell growth than *U*. When *L* and *U* are present together there is some additive effect resulting in even greater cell expansion.

Thus the shape pattern is determined during the period of division very early in ontogeny, although no shape differences are distinguishable in the young leaves (1-2 mm. stage). The ultimate form of the leaf is controlled to a large extent by the amount of cell expansion. Either by longer continued or more rapid division in certain regions than in others a definite pattern consisting of differences in the number of cells per unit area in different regions is laid down in this very early stage. Later during the period of cell expansion, all of the cells of a given tissue tend to expand to approximately the same size. As a result those parts of the leaf which contain more cells per unit area grow more than the other regions. Thus the ultimate shape of the leaf is controlled by the extent

to which cell expansion develops the original pattern laid down by differential cell division.

SUMMARY

Leaf shape in a species cross of *Tropaeolum majus* var. Golden Gleam × *T. peltophorum* var. *fimbriatum* is controlled principally by two genes *L-l* and *U-u*. Evidence is presented to show that *U* produces greater intensity of division in certain areas of the leaf very early in development. *L* has the same effect but to a lesser extent. The main effect of *L* is to produce considerably greater cell growth than *U*. *L* and *U* together result in the greatest amount of cell expansion.

The shape pattern is laid down by differential cell division early in development. The final shape of the leaf is determined by the extent to which cell enlargement develops the potential patterns.

ON THE NASTIC AND TRAUMATIC RESPONSES IN THE PEA TEST¹

Charles L. Schneider

THE "PEA TEST" of Went (1934), a test method for the plant growth hormone auxin, depends on the curvature of longitudinally slit, growing stems (see sketch, fig. 1). Because of released tissue tensions and compressions, the slit halves of the stems curve strongly outward, a new equilibrium position being reached after a short time. In auxin solutions the preliminary outward curvature is soon followed by an inward curvature, *i.e.*, a curvature toward the cut surface. This inward curvature is a result of unequal growth of the "inside" and "outside" layers of tissue and is a function of the auxin concentration.

There has been a series of investigations on the physiological mechanism of this response (Went, 1934; Jost and Reiss, 1936; van Overbeek and Went, 1937; Thimann and Schneider, 1938, 1939; Jost, 1938; Went, 1939). The explanations offered cover most of the conceivable possibilities and include: 1. Growth of the layers of cells near the longitudinally cut surface such that these "inner" cells become more nearly isodiametric; *i.e.*, they decrease in length although they increase in volume. Thus the "inside" becomes shorter and causes an inward curvature. 2. Auxin can enter only through the intact surface (not through the cut surface), and establishes, therefore, an auxin gradient such that the outer layers are stimulated to grow more than the inner. 3. All layers have about equal access to the supplied auxin, but the central and peripheral layers inherently accumulate auxins to different degrees or respond to them to different degrees—*i.e.*, the response is nastic. 4. The injury resulting from slitting reduces the potential growth of cells near the cut—*i.e.*, the response is traumatic.

The first two explanations have already been abandoned. The nastic and traumatic explanations remain; their evaluation in relation to each other is the subject of this paper.

In making this evaluation, allowances must be made for the variable condition of the material used. For example, the finding that a given fraction of the curvature of highly responsive halved stems is the result of trauma or of nastic need not necessarily hold exactly in another case where only slightly responsive halved stems are encountered. In this connection it is of interest that with pea stems the reactivity varies to such a degree as to give the large curvatures reported by Went (1934, 1939) or no inward curvatures at all as reported by Jost and Reiss (1936); similarly with dandelion (*Taraxacum*) flower stalks, either inward pea test curvatures or only extreme outward curvatures can be obtained, in this case, de-

pending on the pre-treatment of the stalks (Jost and Reiss, 1936).

Certain artificially varied conditions of the experimental material are most useful as, *e.g.*, in the analysis below, since they make possible the consideration of each variable separately.

EXPERIMENTAL CONDITIONS AND MATERIALS.—The experiments reported here were performed with plants grown in a dark room at about 25°C. and 80 to 90 per cent relative humidity. Red and orange light only was used for illumination. Where not otherwise stated, the auxin used was 3-indole-acetic acid; solutions were made up in distilled water; the optimum concentration for curvatures with coleoptiles is about 5 mg./l., for stems about 10 mg./l.; no nutrients were added.

Seedlings of peas, *Pisum sativum*, var. Alaska, and of oats, *Avena sativa*, var. Victory, were used. Young oat coleoptiles (from three-day-old seedlings) and the growing parts of pea stems (from seven-day-old seedlings) were used. Coleoptiles were decapitated and slit for a distance of 1.5 cm. beginning at the cut surface; stems were decapitated and slit 2 cm.

THE NASTIC EXPLANATION.—Investigators supporting the nastic explanation have found it necessary to make appropriate experimental balances for tendencies to curve, caused by trauma. This can be done in several ways.

Balancing out the trauma gradient by injury on all sides.—The "inside" injury gradient, caused by slitting the stem, can be counterbalanced by injuring the outside also, as, *e.g.*, by peeling off the epidermis (Thimann and Schneider, 1938; *cf.* van Overbeek and Went, 1937). When this is done, inward curvatures are still obtained. Since all sides are injured, it is simplest to conclude that the curvatures are nastic.

Balanced trauma gradient in a perpendicular plane.—Another way of balancing out trauma effects is by slitting longitudinal ribbons from coleoptiles (fig. 2) of *Zea Mays* (favored because of large diameter, fig. 6) or of *Avena* (Thimann and Schneider, 1939). The inner and outer epidermal layers of these ribbons are thus both left intact. The injury gradients not only balance each other but are perpendicular to the plane of curvature and hence can hardly contribute to the curvature.

However, the cross sectional form of these ribbons changes during the test. The change is in a direction such that the injured surfaces have an inward component; *i.e.*, they take on the shape of the "quarters" of figure 2 (*cf.* Went, who reports the absence of such curvatures, 1939). Presumably this results from an excess lateral growth of the outer layers of the ribbons and hence would be, in itself, a nastic response, and thus is more a support of than a contradiction to the nastic explanation (Thimann and Schneider, 1939). The possibility of inward curvatures arising from this component of trauma can, however, be

¹ Received for publication September 29, 1941.

Experiments reported herein were performed in the Biological Laboratories of Harvard University.

The author wishes to express his appreciation to Professors K. V. Thimann, F. K. Skoog and F. W. Went for criticism during this analysis.

eliminated from the experiment by using "corrected" ribbons such as shown in figure 2. As these ribbons grow, the cut surfaces, which at first have an outwardly directed injury component, became parallel, but inward pea test curvatures are still obtained (Thimann and Schneider, 1939).

Thus whether the injury is balanced out by injury of all surfaces or by appropriate distribution of injured surfaces, strong inward curvatures are still obtained; these curvatures must be largely nastic in origin.

However, the removal of epidermis does more than merely cause injury; it also removes one of the important structural components of the organ. The restraining influence which the epidermis normally exerts on elongation is so great that, upon its removal, inward curvatures are apt to be obtained even in water controls (cf. Went, 1939). Still larger inward curvatures are obtained in auxin solutions (cf. Thimann and Schneider, 1939). It is to be noted that in this particular case, the nastic response must have been strong enough to more than overcome the op-

 Fig. 6. Dimensions of cross sections of *Avena sativa* coleoptile, *Pisum sativum* stem and *Zea mays* coleoptile.
 Fig. 7. Diagram for calculating relation between curvature and differential increase in length.

Reversing the trauma gradient.—An even more striking demonstration that curvature can be caused by a nastic response is obtained by reversing the trauma gradient. To do this, hollow organs such as coleoptiles of *Avena* (Thimann and Schneider, 1938) and flower stalks of *Taraxacum* (Jost, 1938) peeled on the outside can be used. Since a large portion of the "inner" surface of these tubular organs is still covered by the inner epidermis after slitting, the inside is relatively intact and the greater injury, when the organs are peeled, is on the outside; hence, the trauma gradient would tend to cause curvature in the outward direction. Yet these objects give inward curvatures. These curvatures must be of nastic origin.

positely directed tendency for a trauma response. Because of the intimacy of injury with all the remaining tissue and, therefore, greatly reduced growth, this does not provide evidence that nastic is the most effective cause of curvature in the more general case; however, it does provide a special case in which curvature must be accounted for by the nastic response.

A DIGRESSION ON OUTWARD CURVATURES.—Increased outward curvatures obtained with appropriate concentrations of auxins, especially 3-benzofuran-acetic acid, have been considered to be a result of, and support for, the nastic interpretation by Thimann and Schneider (1938). That these curvatures need to be reconsidered, follows from the data pre-

sented in table 1. In this experiment (confirmed by a second experiment), the curvatures of both stems and coleoptiles are compared when peeled and when not peeled for serial dilutions of benzofurane-acetic

TABLE 1. Curvatures of peeled and of ordinary (i.e., not peeled), halved stems and coleoptiles in 3-benzofurane-acetic acid. Measured by stem reference method.

Degrees curvature of	3-benzofurane-acetic acid, mg./l.				
	0	0.08	0.4	2	10
Halved <i>Pisum</i> stems:					
Not peeled	-120	-140	-220	-290	+ 70
Peeled	-260	-270	-120	- 80	+ 10
Halved <i>Avena</i> coleoptiles:					
Not peeled	- 10	- 20	- 20	-100	-163
Peeled	+120	+150	+140	+130	+190

acid. (The benzofurane-acetic acid crystals were part of the same sample as used by Thimann and Schneider, 1938.) If the increased outward curvatures of ordinary halved organs were nastic in origin, similar increases in outward curvature would be expected with the peeled halves. As can be seen from the table no such trend was found. Perhaps, rather, the outward curvature obtained with not-peeled halves in solutions of this auxin or in low concentrations of other auxins is due to easier entry of auxin on the injured side. Whether this be the correct explanation or not, the outward curvatures obtained with this auxin can no longer be considered as adequate support, in themselves, for the nastic explanation.

THE TRAUMATIC EXPLANATION.—For investigators supporting the nastic explanation, no ways have been found for completely eliminating or balancing out the nastic response. Whenever a trauma gradient is produced, a nastic gradient is also produced because of affecting at least one layer of tissue to produce the trauma. For experimental investigation, however, peeling the epidermis off one side of a pea stem (Went, 1939) approaches this state closely, and inward curvatures are obtained in auxins (*cf.* also Thimann and Schneider, 1938, for the *Avena* coleoptile). Since the organ is structurally still nearly symmetrical when the epidermis is thus asymmetrically removed, the curvature produced must be largely due to the trauma gradient.

Decrease of growth by injury.—In favor of Went's trauma explanation (1939) is his observation that longitudinally slit stems grow less in response to auxin than do stems that are not slit. This reduction of potential growth by injury and the reasonable assumption (backed up by deductions from experiments) that there is a trauma gradient away from the site of injury, led Went (1939) to the conclusion that injury is responsible for auxin curvatures in the pea test.

Additional evidence for this view is provided by the measurements of van Overbeek and Went (1937;

cf. Went, 1939). In optimal concentrations of auxin, the "outside" layers of halved *Pisum* stems grew the same amount as intact control stems, but the tissue near the slit surface grew much less. Although this difference in growth between the layers farthest from and those nearest to the slit may be partly explained by nastic responses, the data are highly consistent with the postulate of a trauma gradient directed away from the site of injury.

Further, by determining the actual elongation of inside and outside, Went (1939) was able to show that the responsiveness of tissue near the wound decreased more rapidly with time after making the wound than did the responsiveness of tissues farthest from the wound. This trauma effect is complex, the more apical regions responding differently than the older regions below (Went, 1939).

Decreased responsiveness to auxin as a function of amount of injury.—That relatively more injury causes greater decrease of growth can be demonstrated by longitudinally slitting a segment of stem to one side of the axis, with the slit not extending quite to the ends of the segment (fig. 3). This gives two strips, one thick and one thin, attached to each other at both ends. Both strips have the same absolute injury, since they are from opposite sides of the same cut. On allowing growth to proceed, especially in optimal concentrations of auxin, the result is a bow shaped object (obtained repeatedly) with the thinner strip forming the string of the bow (fig. 3). According to the nastic explanation the thinner strip should have grown most, since it is largely "outer" tissue. That the thin strip grew least must be interpreted to mean that the trauma effect is large enough to more than offset the nastic effect.

Quantitative relations between growth and amount of injury.—Stem and coleoptile sections of known length (2.0 cm. for stems and 1.5 cm. for coleoptiles) were slit as shown in figure 4 and placed in optimal concentrations of auxin (5 mg./l.). By leaving unslit portions at both ends, the sections remained fairly straight and could be further straightened beside a rule to estimate the amount of elongation. The injury can be increased by slitting a second time in the perpendicular plane. For the coleoptiles, the amount of injury can be still further varied by making the single slit either in the plane of the vascular bundles where the coleoptile is thickest (*cf.* fig. 6) or in the plane at right angles to this where the coleoptile is thinnest. (In figure 5, coleoptiles slit in these two ways are plotted as 4/3 and as 2/3 of a cut respectively.) The resulting effects of injury on the straight growth in auxin are plotted in figure 5. The elongation for the injured sections is, in each case, plotted as percentage of the elongation of the controls. The actual elongation of the *Pisum* controls was 40 per cent and of *Avena* 26 per cent over the original lengths. The results are as though, under the conditions investigated, the decrease of potential growth by trauma, for a given volume of tissues, is approximately proportional to the area of injury (fig. 5).

Trauma index for coleoptile and stem.—The growth decrease relative to the amount of injury and tissue involved can be designated as the trauma index. Its value is measured by the slope of the curve of figure 5; it is about the same for *Avena* coleoptiles as for *Pisum* stems under these conditions of etiolation.

SIMULTANEOUS EFFECT OF NASTY AND TRAUMA.—In summarizing the above evidence, it is to be seen that there need be no mutual contradiction of the nastic and traumatic explanations. Thus:

In certain special cases where the injury gradient is balanced out or reversed, the curvature of slit stems must be almost entirely nastic.

Under the conditions of the pea test, trauma reduces the ability of tissues to grow, and it appears that this trauma effect has a gradient away from the site of injury; therefore, in cases where injury is asymmetrical, trauma should tend to cause curvature. In one special case the nastic effect can be largely balanced out; the curvature in this case must be largely traumatic.

Since nastic and traumatic responses may be considered as experimentally established and as supplementary rather than contradictory, the pea test problem becomes one of estimating the relative importance of the nastic and traumatic responses.

NASTIC RESPONSE AS THE STANDARD FOR COMPARISON FOR THE RATIO, NASTY/TRAUMA.—The special cases (above), in which curvature is entirely or predominantly nastic, can be used to estimate what fraction of the curvature of the more general cases is nastic. The evaluation will depend on setting an upper limit to the ratio of effectiveness for nasty/trauma. An exact evaluation is not possible here, both because of the complex mathematical analysis and because of complicating biological factors. Where uncertainty arises, favor is shown toward nasty; in the end this gives small error, because, at best, for the general case, nasty turns out to be the lesser cause of the curvature.

Comparison of ribbons and of halves of coleoptiles.—If we consider that the portions of halved coleoptiles near the slit are the equivalent of "inner" tissue and that these grade into "outer" tissue at the middle of the semi-circular arc (see fig. 2), then the distance separating inner and outer tissue, in the plane of curvature is the distance r , the radius of the coleoptile. In the ribbons, inner and outer tissue are separated by not more than the distance t , i.e., the thickness of the coleoptile tissue in the region from which the ribbon was taken (see fig. 6).

The mathematical analysis comparing the curvatures of these halves and ribbons is analogous to that for the curving of a bi-metallic strip (ribbon) as compared with the curving of a bi-metallic half-cylinder made by inrolling of the strip. The same geometric relations that allow only a small curvature of the bi-metallic half-cylinder should allow only a small curvature of the halved coleoptile. For the present, however, both the ribbon and the half-cylinder will be considered as simple, strip-like structures grad-

ing from "inner" to "outer" layers. While this assumption does not permit an exact analysis, it makes possible the estimation of an upper limit.

The curvature caused by unequal extension of the "inner" and "outer" layers can be calculated by the formula: $a = k \times \Delta l / t$, where a is the angle of curvature, k is a constant, Δl is the differential increase in length of the "inside" and "outside," and t the distance between the inner and outer layers (fig. 7) (see Purdy, 1921).

Using this formula to deduce the ratio of curvature to be expected for halved coleoptiles and for ribbons, we find the ratio to be t/r . Actual measurements of t and r for *Avena* (fig. 6) give a ratio of the order of 1:4 (0.16/0.64). Hence, if the nastic influence were also the *only* cause of curvature in the halves (as in the ribbons), the ratio of curvatures of halves and ribbons should be 1:4. On the contrary, the relative curvature for quartered against halved coleoptiles is about 1:1; i.e., the halves curve about four times as much as could be accounted for on the basis of nastic responses alone; i.e., only about 0.3 (one-fourth) of their curvature can be accounted for as nastic. The remaining 0.7 must be accounted for as traumatic.

In obtaining this ratio, quartered coleoptiles are considered the equal of ribbons. This is not strictly true, for quarters curve more than ribbons (averages of 180° as against 160° in one experiment, 180° as against 60° in another), but the deviation is in the direction to give the nastic view the advantage and, therefore, can be used in setting an upper limit to the importance of the nastic effect. Using this assumption, the ratio 1:1 can be deduced from figure 3 of Thimann and Schneider (1939); its actual value depending on the choice of control values for the quarters. It might be argued that taking the total differences between water controls and optimal response in this figure would give a value of 1:2. Even on such a basis, only 0.5 of the curvature could be accounted for as nastic, but this comparison would be misleading because the halves are prevented by their geometric structure from giving as large outward curvatures as the quarters; the epidermis especially tends to restrict outward curvatures of the halves. (For similar restrictions in the case of halved pea stems, see results of Thimann and Schneider, p. 625, 1939. It is shown there that the tension of the epidermis near the cut surface prevents full extension of the "inner" layer, thus limiting the magnitude of the outward curvature.) Thus the lower half of the curve for quarters is mechanically impossible for the halves, although physiologically it is to be predicted. Fortunately, the upper parts of the curve for halves and quarters coincide so that this mechanical difficulty can be eliminated from the calculations by using as control value for both halves and quarters either zero curvature or the control value of the halves. This gives the ratio quoted above—about 1:1.

It will be noted that the original assumption above gives the nastic explanation much advantage in this discussion. Thus for the halved coleoptiles, the tissue

nearest the cut has been considered as "inner" tissue and the tissue farthest from the cut has been considered as "outer" tissue. But, because of its component of outer tissue, the "inside" of halved coleoptiles would tend to grow more than would purely inner tissue and, conversely, the "outside," because of its component of morphologically inner tissue, would tend to grow less than would purely outer tissue. Taking this added advantage for the nastic explanation into account, the expected ratio of t/r for the postulated case of no trauma response in the halved coleoptile would be effectively smaller than 1:4; hence, even less than one-fourth of the curvature could be accounted for by the nastic response.

This analysis ascribes so large a rôle to the trauma response as to make independent analysis from other sources of great interest.

Trauma in the curvatures of slit coleoptiles as well as in slit stems.—Besides the measurements plotted in figure 5 which show that trauma affects growth of sections of *Avena* coleoptiles and of *Pisum* stems to the same degree, it follows from a consideration of geometric structure that trauma should play about as important a rôle in the curvature of halved *Avena* coleoptiles as in that of halved *Pisum* stems. This contradicts the contention of Thimann and Schneider (1938) that injury is unimportant in the curvatures of halved coleoptiles because of the small amount of injury involved. The injured area of the coleoptile is small, but so is the amount of tissue.

For the halved coleoptile the tissue farthest from the slit is at about the same distance from the site of injury as in the halved pea stem. Thus the shortest distance, *through coleoptile tissue*, from the slit to the farthest "outside" tissue is a little less than 1 mm. (fig. 6: $2\pi r/4 = \pi 0.64/2 = 1$ mm.). In the halved pea stem the shortest distance (the radius of the stem) is also about 1 mm. Thus the same geometric structure that reduces the absolute amount of injury for the halved *Avena* coleoptile assures distribution of injury in such a manner as to compare physiologically with that of the halved pea stem.

Because of the smaller radius of the coleoptile, other things being equal, this results in an even steeper component of trauma gradient in the plane of curvature for the coleoptile than for the stem. Therefore, although there is less absolute injury upon slitting a coleoptile than upon slitting a stem, the effect of trauma on subsequent curvatures can be at least as large, and the trauma explanation of curvatures is certainly no less appropriate for halved coleoptiles than for halved stems.

Peeled vs. not-peeled halves of stems.—A similar comparison can still be made by considering the curvature of peeled halved pea stems as nastic in origin and that of ordinary halves as nastic plus traumatic in origin. The data of Thimann and Schneider (fig. 2A, 1938) obtained by the "inflection reference" method is suitable for this purpose. The inward curvature of peeled halves in auxin is 100° , that of ordinary halves 250° . Presumably, the increase of 150° is the result of the trauma gradient; hence, the ratio

of nasty/trauma is $1/1.5$; i.e., the curvature of halved pea stems would be $2/5$ (i.e., 0.4) nastic and $3/5$ (i.e., 0.6) traumatic in origin. As seen below this too probably favors the nastic interpretation.

As in the comparison of ribbons (or quarters) and halves of coleoptiles above, the differences of the structure of the curving elements becomes important. The outward curvature of ordinary halves is greatly restrained by the epidermis as compared with that of the peeled halves (cf. Thimann and Schneider, p. 625, 1938), and direct comparison of water controls of peeled and ordinary halves by the "stem reference" method is thus made impossible. Measurements based on the inflection reference method eliminate that part of the curve which is structurally impossible for the ordinary halves to attain.

Just as removal of the epidermis allows an increase of outward curvatures of water controls, it may also allow increase of inward curvatures in the auxin treatment. This would place the value of 0.6 obtained above, for the traumatic effect as a minimal estimate.

TRAUMA RESPONSE AS STANDARD FOR COMPARISON FOR THE RATIO, NASTY/TRAUMA.—In all of the above cases, the analysis has depended on comparison of curvatures with a special case in which the cause of curvature was entirely or predominantly nastic. The fraction of the curvature that could not be accounted for as nastic in the more general case was then concluded to be of trauma origin. The over-all findings indicate that probably less than one-half of the curvature of ordinary halved organs in the pea test is nastic; the remainder, more than one-half, is concluded to be traumatic. To check this conclusion it is desirable to make a similar comparison in a case in which the nastic response is largely balanced out and trauma is the predominant cause of curvature. The case most nearly approaching balancing out of nasty but having trauma is that in which the epidermis is peeled off one side of an (whole, i.e., not slit) organ. In this case, the tissues, with the exception of the epidermis, are so symmetrically disposed as to balance out nearly all of the nastic tendencies for curvature. The resulting curvatures must be predominantly of trauma origin.

Making use of the formula of Purdy, quoted above, that fraction of the curvature of ordinary halves which can be accounted for as traumatic, can be estimated by comparison with not-slit organs which are peeled on one side. If it be assumed, among other things, that in both cases the tissue near the wound is strongly affected by trauma and that the tissue farthest from the wound is free of trauma effect, it would be expected that the halves would curve twice as much from trauma alone as would the not-halved organs which are peeled on one side. Data on this point for *Pisum* stems are available from Went (1939, fig. 3). The ratio is actually $1.5/1$ (c. 330° to 220°). Similar data for coleoptiles are available for *Avena* from the experiments of Thimann and Schneider (1938, fig. 8 and 3). In this case the ratio is $1.6/1$ (c. 420° to c. 260°). If these data were used directly, it should be concluded that at least all of

the curvature of ordinary halves is of trauma origin because, by deduction from the formula of Purdy, a ratio of greater than 2/1 would be required before any of the curvature of the ordinary halves would be left to be accounted for by the nastic effect. However, it will be noted that a direct comparison is not valid because of the shape of the cross section of the organs that are peeled on one side. If the organs are peeled on half of their circumference, then the wound area is not localized at a distance of a full diameter from the intact side; much of it is closer. This effectively reduces the ratio of curvatures to be expected on the basis of trauma alone and favors the nastic explanation; the lowest value that could be expected would be 1/1 if the trauma effect from the peeling extended so far around as to be almost as effectively distributed as in the ordinary halves. Using this extreme assumption, the ratios of 1.5/1 and 1.6/1 would indicate that about 0.7 of the curvature of halved stems and 0.6 of the curvature of halved coleoptiles is of trauma origin. The remaining fractions, 0.3 and 0.4, would then be concluded to be of nastic origin. This distribution agrees well with the estimates obtained above, in which comparison was made with special cases wherein the nastic response was the predominant cause of curvature.

CONCLUSION.—In comparing the effectiveness of the two causes of curvature in the pea test, only the most pertinent evidence for the relative evaluations have been considered. In the literature referred to are many further data and deductions of greater detail.

The conclusions arrived at here on relative effectiveness of the nastic and the traumatic responses in the ordinary pea test are essentially for optimal auxin treatment since the evaluations depend on the difference between curvatures of halves in water and in auxin solutions of concentrations in which optimal responses are obtained.

The deductions are applicable to the slit halves of organs used in the pea test and are only indirectly applicable to the growth of intact organs.

For the ordinary pea test, whether performed with slit stems or coleoptiles, the above evidence indicates that less than half of the curvature is of nastic origin, more than half of traumatic origin. The results are accumulated in table 2.

TABLE 2. *Fractions of curvature caused by nastic and by traumatic responses in the pea test. Values favor the nastic explanation and hence set an upper limit for the nastic response.*

	Nastic	Traumatic
When standard for comparison is of nastic origin:		
Coleoptiles of <i>Avena</i> :		
Ribbons vs. halves.....	0.3	0.7
Stems of <i>Pisum</i> :		
Peeled vs. not peeled halves	0.4	0.6
When standard for comparison is of trauma origin:		
Coleoptiles of <i>Avena</i> :		
Thick vs. ordinary halves...	0.4	0.6
Stems of <i>Pisum</i> :		
Thick vs. ordinary halves..	0.3	0.7

SUMMARY

The chief points establishing the nastic and traumatic causes of the curvatures of the pea test are summarized. These involve special cases wherein the curvature is predominantly either nastic or traumatic in origin together with demonstrations of a trauma effect.

The nastic and traumatic responses to auxin in the pea test are considered as complementary rather than contradictory.

From a direct measurement of the effect of injury on growth during optimal treatment with auxin, it was found that growth is affected to about the same extent in both *Pisum* stems and *Avena* coleoptiles by the same relative amounts of injury.

It was found by comparison of special cases where nastic is the only, or nearly the only, cause of curvature that values for the fraction of the curvature caused by the nastic response of ordinary halved *Avena* coleoptiles and *Pisum* stems, tend to be well below 0.5. The remainder of the curvature, more than 0.5, is concluded to be of trauma origin. These estimates are supported by a similar analysis from the opposite direction in which a largely traumatic response is used as the standard of comparison.

THE INFLUENCE OF COPPER AND IODINE ON THE GROWTH OF AZOTOBACTER AGILE ¹

J. C. Lewis

AZOTOBACTER AGILE apparently does not require appreciable amounts of iodine in its nutrition (Lewis and Powers, 1941). The organism has been periodically subcultured over a period of one year in a special medium containing on the order of only one part per trillion (1×10^{-12} gms. per ml.) of iodine, without progressive reduction in growth-rate or maximum turbidity of the cultures. Nevertheless, iodine has been found to increase both growth-rate (Lewis and Powers, 1941) and final yield (Stoklasa, 1926; Itano and Matsuura, 1933; Greaves, 1933) of *Azotobacter* under certain conditions. It seems likely that such stimulations are due to actions other than satisfying a deficiency of an essential nutrient factor.

An observation during early experiments indicated that a stimulation of growth-rate of *Azotobacter agile* by iodine might be related to the concentrations of certain trace elements with which the culture medium was supplemented. Experiments were, therefore, conducted to determine the minimum toxic concentrations of several nutritionally important trace elements, and to test possible interactions with potassium iodide.

METHODS.—*Azotobacter agile* was inoculated into 500 ml. cotton-plugged Erlenmeyer flasks containing

¹ Received for publication October 2, 1941.

Published as Technical Paper No. 390 with the approval of the Director of the Oregon Agricultural Experiment Station as a contribution of the Soils Department and the Department of Agricultural Chemistry. The author desires to thank Dr. W. L. Powers, under whose guidance the work was begun; Dr. J. R. Haag, in whose laboratory the work was continued; and Dr. W. B. Bollen and Dr. C. P. Hegarty for their interest and advice.

140 ml. aliquots of the experimental medium, from a two- to three-day-old subculture of the organism which had been carried for extended periods on "iodine-free" medium. Growth was measured, after it became visible, in early experiments by microkjeldahl nitrogen determinations and by plate counts, in later experiments by turbidity measurements, using a commercial photoelectric colorimeter with a wide-band filter (maximum transmission at 420 mμ). Since the effects investigated were most pronounced in the earliest visible growth stages, and did not, in general, affect crop yields, measurements in later experiments were sometimes restricted to the early growth stages.

The nutrient medium was prepared from specially purified "iodine-free" chemicals. It contained on the order of one part per trillion (1×10^{-12} gms. per ml.) of iodine. The equivalent of 1.1 per cent by weight of absolute ethyl alcohol was added after sterilization as a carbon and energy source. The pH was adjusted to 7.0 ± 0.1 . Trace elements were supplied in amounts to be mentioned later. The cultures were grown at room temperatures. Purification methods for the nutrient chemicals, the nutrient formula, and cultural details have been previously described (Lewis, 1940; Lewis and Powers, 1941).

RESULTS.—An experiment showing an effect of added iodine on the growth of *Azotobacter agile* as a function of the growth period is presented in table 1 (experiment 1). Trace elements were added at the following concentrations: Mn, 0.5; B, 0.5; Zn, 0.05; Mo, 0.05; Cu, 0.02 ppm. The effects of potassium

iodide are most marked in the earliest stage, while these effects tend to disappear as the cultures attain their maximum growth. For further experiments, therefore, data will be presented for only the earlier growth stages within the range of the photoelectric colorimeter.

A second experiment (experiment 2, table 1) involved trace elements at one-fifth the concentrations used above. In this experiment, the magnitude of the iodide stimulation after two days' growth was smaller than in the preceding experiment, although still statistically significant. Also, the optimal iodide concentration was now found to be 0.0001 to 0.001 ppm. in contrast with the optimum at 0.1 to 1 ppm. in the preceding experiment.

These results prompted experiments to determine the minimum toxic levels of the trace elements with which the basal medium was supplemented. In such experiments the concentrations of trace elements were varied individually in the presence of optimal levels of the others. The following concentrations appeared to be within the optimal range and were used as basal levels in further experiments: Mn, 0.05; B, 0.5; Zn, 0.005; Mo, 0.005; Cu, 0.004; and Fe, 1 ppm. The concentrations of trace elements that gave an approximately 50 per cent reduction of growth at the stage investigated were as follows: Mn, 10; B, 25; Zn, 0.5; Mo, 10; and Cu, 0.4 ppm.

In general, a toxic concentration of a trace element either did not affect the mature yields or else prevented all growth. Cultures containing 5 ppm. of zinc showed no growth in eleven days, while 10 ppm. of iron and 2 ppm. of copper gave similar results. How-

ever, as will be mentioned later, 1 ppm. of copper in another experiment prevented growth for two weeks, after which essentially normal crop yields were attained. A small reduction in eleven-day crop yield occurred with 50 ppm. of manganese. The additions of the highest rates of iron, zinc, boron, and manganese were accompanied by precipitation.

Characteristic colors developed in the medium of the mature cultures in the presence of the higher levels of the trace elements. Molybdenum gave a bright salmon-orange color. Manganese gave a dirty pink color. Copper and iodine tended to give tan colors. Zinc cultures became very clear, while the normal cultures had a drab gray color. Iron-deficient cultures showed a characteristic pronounced greenish-yellow color. Occasionally the mature stock cultures would suddenly begin to produce a pink pigment that would finally give them a deep wine color. The first time this was observed it occurred simultaneously and to approximately the same degree in sixty different flasks that had been inoculated from the same colorless culture.

Although no special precautions were taken to obtain a basal medium low in trace elements other than iodine, a strong inhibition of growth occurred in the cases of zero and 0.1 ppm. of added iron while 1 ppm. was optimal. Likewise, zero and 0.00005 ppm. of added molybdenum were decidedly suboptimal, while 0.0005 ppm. was only slightly so. In one experiment, growth was approximately one-half maximal in the absence of added copper, while 0.001 ppm. was optimal. It should be emphasized that these deficiencies affected only the extent of growth at an early stage

and did not affect the final yields. (Data for these experiments are summarized in table 2.)

To investigate possible effects of iodine, experiments were conducted to show the effect of various concentrations of iodide in a medium containing a sufficient concentration of the trace element under consideration to give an approximately 50 per cent reduction in growth at the desired growth stage. In such solutions, the other trace elements were present at "optimal" concentrations previously given. The results of several of these experiments are given in table 3. The effect of iodine in counteracting the toxicity of copper is evident. No interactions appear to exist between iodine and manganese or zinc toxicity. Molybdenum, boron, and iron were not investigated in this respect.

An interesting effect was found in the presence of 1 ppm. of copper. These cultures, regardless of iodine treatment, showed no growth within the period ordinarily required for maturity. The cultures were saved, however, and on about the fourteenth day growth appeared in one of the cultures, which then rapidly attained the normal maximum growth. On further standing, growth appeared in the other cultures. This extended lag period was definitely shorter in the presence of iodine. The difference may be expressed on the basis of the time required for the culture to reach half-maximum growth. This period was 32.6 ± 2.5 days for the controls lacking iodine, 22.5 ± 6.0 days in the presence of 1 ppm. of iodine, and 21.2 ± 1.1 days in the presence of 10 ppm. of iodine. The data referring to this experiment in table 3 were chosen to represent a period of maximum difference between the treatments.

DISCUSSION.—It seems probable that the results found with iodine and copper were due to actions of the trace elements on the lag growth phase of the organism. This is supported by the experiment with 1 ppm. of copper in which the lag phase was greatly extended. In this case, only the lag period was altered by iodide additions, the logarithmic growth-rate was unaffected. For this reason, the sensitivity and magnitude of the responses may well have been greater had still earlier growth stages been investi-

gated. Likewise, it may be presumed that size of inoculum and physiological age of the inoculum were important factors. Attention to such factors was limited to keeping them constant in any given set of experiments. Difficulties in reproducing the same degree of toxicity with a given concentration of an element were probably partly due to such factors.

The iron, molybdenum, and copper deficiencies noted during early but not during final growth stages are also of interest here. A similar observation has recently been made by Wooley (1941) with respect to the manganese requirement of *Lactobacillus casei*. The situation seems to be analogous to the effect on various microorganisms of certain organic growth factors whose addition may stimulate during early growth stages but be without effect on the maximum yield. Whether such results are due to a decreased lag period or an increased logarithmic growth rate remains to be seen.

Although the response of copper toxicity to iodine additions was clear-cut, the magnitude of the response, as well as the toxicities of given levels of copper, was variable, especially for lower copper concentrations. This was probably due to rapid removal of copper from solution by adsorption and precipitation, as well as to the factors mentioned above.

The manner of interaction of copper and iodine is not known. It may be pointed out that cupric ions and iodide ions react to form relatively insoluble cuprous iodide and free iodine.

Not all of the responses to iodides observed in these experiments are explainable on the basis of copper-iodide interaction. For example, in one experiment a significant response to 0.0001 ppm. of added iodine was noted. This is approaching the maximum dilutions at which the most active organic growth factors give perceptible effects. It has not been possible to demonstrate the copper-iodide interaction with either extremely low copper or iodine concentrations. It is likely, in view of the number of relatively insoluble iodides, that interactions exist between other metals and iodine. That this is true for silver ions and iodides has been noted by Stein-

berg (1935) in studying the growth of *Aspergillus niger*.

Preliminary experiments with flax and corn failed to demonstrate the copper-iodide interaction. The rapid precipitation of copper in our solutions, sometimes essentially complete within twenty-four hours, was probably the main reason for this result. The relatively greater sensitivity of these plants to iodine and lesser sensitivity to copper were probably also important. Nevertheless, it is likely that this type of action of iodine has entered into various plant nutrition studies with trace elements. Thus the experiments of Meyer (1931) with buckwheat show a toxicity in the presence of 0.125 ppm. of copper which is overcome by the further addition of 0.25 ppm. of iodine. The occasional occurrence of toxic substances in distilled water has been a question of some concern

to plant physiologists; in this connection, inhibition of such toxic actions should receive equal consideration.

SUMMARY

An interaction between copper and iodine in the early growth stages of *Azotobacter agile* has been demonstrated. The action of copper appears to manifest itself in a lengthened lag growth phase, while this effect is reduced by iodine. Such actions should be considered before stimulating effects of iodine are interpreted as evidence of the essential nature of iodine in plant or microbiological nutrition.

SURFACE RELATIONSHIPS OF ROOTS AND COLLOIDAL CLAY IN PLANT NUTRITION ¹

Wm. A. Albrecht, E. R. Graham, and H. R. Shepard ²

THE RECENT increase in national concern in regard to the losses of soil by erosion may well lead us to appreciate the fact that the land has gone nude because cover growth is prohibited by man's management and because of the declining store of fertility in the soil. This fertility consists of the chemical elements which the soil contributes to the plants. This contribution to any single crop is small. For many plants it represents but five per cent of the total dry matter in the plants, or even less. Air and water worked up into chemical combination by the energy of the sun constitute the bulk of most plants. This process of carbohydrate synthesis—the dominant one of all plant growth activities—can be carried out, or even initiated, only as the soil contributes from its store of essential plant nutrients. The declining supply of soil fertility must of necessity shift the plant population more and more to those kinds whose final composition represents less from the soil and more from the air and water. That is, considering

rather broadly the functions of the nutrient elements within the plant, the crops must shift toward those with less of protein and mineral content and more of materials with mere fuel significance. Naturally, lessened possibilities for proper animal and human nutrition must accompany these changes. In the light of these considerations, the contributions by the soil to plant contents, the mechanisms through which such contributions are made, and the relative supplies within the soil become of much concern to all of us.

MORE RECENT CONCEPTS OF MECHANISMS OF NUTRIENT DELIVERY BY THE SOIL.—With the increased knowledge of the colloidal behavior of the clay separate of the soil (Bradfield, 1923) and of the exchange of adsorbed ions between colloids through their contact (Jenny and Overstreet, 1938), it is no longer necessary to consider the supply of nutrients in the soil as limited to those in the displaceable soil solution. The immediate stock is not only that which is in true solution or that which would leach out, but also that which is exchangeable by other ions, more particularly those of similar electric charge. This exchangeable stock is of far larger magnitude than that of the simple solution. For better understanding

¹ Received for publication October 17, 1941.

Contribution from the Department of Soils, Missouri Agricultural Experiment Station, Columbia, Missouri, Journal Series No. 785.

² Professor, Instructor, and Graduate Student in Soils, respectively.

of plant nutrition we must understand this cationic exchange behavior in which the soil gives up its adsorbed nutrient elements of positive charge for hydrogen, which is a cation contributed in exchange by the plant. Whether anionic behavior is similar is a question that is awaiting specific information, though it is not unreasonable to anticipate some likeness.

PLANT NUTRITION MAY BE MAINLY A SURFACE PHENOMENON.—If the cations of nutritional value are given up by the soil through this exchange in which the hydrogen, coming from the plant's liberation of carbon dioxide, displaces them from the clay in direct contact with the root, then the extent of the performance resolves itself into one of surface nature and areas. The rate of reaction, as well as the total of cations taken from a given soil by the plant roots, is then a question of magnitudes of root and clay surfaces in contact, and of the kinds and concentrations of adsorbed ions on the clay.

Should all other factors be removed from consideration, it will be of theoretical interest, at least, to view plant nutrition as largely a surface phenomenon determined by the surfaces of the plant root, and the surfaces of the soil or colloidal clay on which the exchange activities are possible. The following discussion uses some recent root surface data and some clay surface values in an attempt to elucidate plant nutrition hypothetically as an exchange phenomenon.

SOME ROOT SURFACE VALUES FOR PLANTS.—The studies by Dittmer (1940) give values for the root and root hair surfaces for soybeans, oats, rye and bluegrass in a specific soil. Since, in the last three of this group, more than 90 per cent of the surface of the root system is that of the root hairs, the values for the entire root system will be used, even though adsorptive activities are commonly attributed to the root hairs only. The values for the total surface of the roots are given in table 1 with figures ranging from 1.0 to 25.6 square centimeters per cubic centimeter of soil.

TABLE 1. *Total root surfaces of different crops in given soil volumes.*

Crops	Square inches per		
	42 cu. in. of soil	Cu in. of soil ^a	Sq. cm. per cc. of soil ^a
Soybeans	106.1	2.5	1.0
Oats	583.4	13.9	5.9
Rye (winter)	1,267.9	30.0	11.8
Bluegrass (Kentucky) .	2,779.9	66.1	25.6

^a Values are calculations from those by Dittmer.

SOME SURFACE VALUES FOR COLLOIDAL CLAY.—As for the surface offered by the soil for contact with the roots, this can be determined from the size of the particles of the colloidal clay. Numerous studies of this fraction of the Putnam silt loam subsoil have been made (Marshall, 1936). If we disregard the sand and silt fractions of this well weathered soil for their exchange activities, and if we accept the

general fact that this clay constitutes one-sixth of the surface soil of the Putnam profile, then the clay content will amount to .222 gm. per cubic centimeter of soil which weighs 1.33 gms. By placing the approximate general size of the clay particle at one-tenth micron, or .00001 cm. (10^{-5} cm.), as the effective diameter, the value will be that into which about 35 per cent of the clay falls. The shape of the particles is of disc nature (Marshall, 1941), but for the purpose of simpler concept, we may visualize the shape as cubical with faces of the above effective diametric dimensions, *viz.*, 10^{-5} cm.

SMALL PORTION OF SOIL'S CLAY CONTENT IS IN ROOT CONTACT.—Should we visualize that these colloidal clay cubes are carrying their adsorbed nutrients on their surfaces and are in contact with the root with one face of the cube against it, then each particle would present a contact area of 10^{-10} sq. cm. According to the root areas given in table 1, the numbers of clay particles which would be required to cover the entire root area in a cubic centimeter of soil are those given in table 2 (column 1). With a specific gravity of 2.5 and a particle volume of (10^{-5} cm.)³, the weight of the clay in root contact for the root surface per cubic centimeter of soil volume would be that given in the same table (column 2). Since there is but .222 gm. clay in this soil volume, then the clay in contact with the roots represents but a small percentage of the soil's total clay, or those fractions of per cent given also in table 2 (column 3).

ADSORBED NUTRIENTS REPRESENTED BY CONTACT EXCHANGE.—As a means of determining the amount of nutrients delivered by the clay surface in root contact, we may use the total exchange capacity of the clay, *viz.*, .65 M.E. per gm., or .65 pound equivalents per thousand pounds of clay, as has been reported from many determinations (Ferguson and Albrecht, 1941). In a cubic foot of soil weighing 83.2 pounds (1.33, volume weight, \times 62.4 pounds per cubic foot of water), of which one-sixth, 13.85 pounds, is clay, the exchange equivalents would be but .009 pounds ($13.85 \times .65/1,000$). When considered per acre six inches deep, this would be but 196.02 pound equivalents ($.009/2 \times 43,560$ sq. ft. acre area). Should this clay be saturated completely with calcium, then the clay per acre six inches deep would contain twenty times the equivalent, or 3,920 pounds of exchangeable calcium. If the percentage of surface in contact as given in table 2 is applied to this calcium value and if the calcium on the clay surface in contact is completely taken by the plants, then the amount of calcium so obtained by the different crops would be those in table 3 (column 1).

That removal to completion, or 100 per cent, by exchange is not easily conceivable as common occurrence was shown in the work by Ferguson and Albrecht (1941), where only 85 per cent of the exchangeable calcium was taken by three successive crops, but not without significant irregularities in plant growth. A single crop took but 40 per cent. If we should assume as usable only 85 per cent of the adsorbed calcium on the clay faces in root contact,

TABLE 2. *Clay in contact with plant roots expressed as numbers and weights of clay particles and per cent of clay in the soil.*

Crops	Clay in root contact per cubic centimeter of soil expressed as		
	Number of clay particles ^a	Weight, ^b gms.	Per cent of total clay ^c
Soybeans	1.0×10^{10}	$.25 \times 10^{-4}$.011
Oats	5.9×10^{10}	1.47×10^{-4}	.066
Rye (winter)	11.8×10^{10}	2.95×10^{-4}	.133
Bluegrass (Kentucky)	25.6×10^{10}	6.40×10^{-4}	.289
	(Column 1)	(Column 2)	(Column 3)

^a Root area in sq. cm. divided by area of face of particles (10^{-10} sq. cm.).^b Number of clay particles $\times (10^{-5})^3 \times 2.5$.^c Weight of clay particles $\times 100/.222$.

the amounts taken per acre would then be those in table 3 (column 2). If only a single crop had been grown with 40 per cent of the exchangeable calcium taken, then only those amounts as given in the table (column 3) would be taken per acre six inches deep.

NORMAL CALCIUM USE BY CROPS IS GREATER THAN THE DELIVERY BY DIRECT CONTACT ONLY.—When one considers the acre yields of these crops and the calcium contents of their above-ground parts as found by chemical analyses, then the fact is immediately evident that the soil delivers to this crop portion and particularly to the entire plants, roots and tops, more calcium than would be provided if only that adsorbed on the clay surface in immediate root contact were taken. In table 3 (column 4) are given the amounts of calcium commonly found in these crops as harvested from conservative acre yields.

MOVEMENT BETWEEN CLAY PARTICLES BY ADSORBED IONS IS SUGGESTED.—If these figures represent the facts, they suggest that there must be adjustments in concentration of the adsorbed ions, particularly nutrient ions, even on the colloidal clay surfaces of the individual particles and between the different clay particles. Calcium removal, according to these calculations for the commonly harvested parts of the crop, suggests adsorbed ion movement toward the roots through more than a few layers of clay particles, especially for the soybeans. When the entire plants are considered, the evidence is more convincing. Still further, the movement of ions cannot be wholly from clay in a silt loam of which only one-sixth is clay. Some of the root area is in contact with silt. From the mineral faces of the silt it would seem that the source would be the face in contact only. With the silt so little active, the clay

must be all the more active in the movement of adsorbed ions over the particle, and through several layers of particles.

MOVEMENT OF CATIONS BETWEEN CLAY PARTICLES DEMONSTRATED.—That such movements of ions from one clay area to another are possible has been demonstrated. By bringing a sand-clay mixture, the clay of which was saturated by calcium, into contact with a similar one saturated by hydrogen, the migration of these cations from one location to the other within a period of thirty days was demonstrated. Calcium had moved more than two inches into the hydrogen clay area, and the hydrogen had similarly moved into the calcium clay area. These migrations took place when all the calcium was adsorbed, and when no significant solution activity can be considered as playing a rôle in this exchange.

Cationic movement of adsorbed nutrients is a possibility, then, along the faces of the clay particles, if such activity may be visualized as occurring in the exchange atmosphere or in the adsorption layer on the face of the clay crystal, and if these plant and soil behaviors may be considered as evidence.

MOVEMENT OF IONS FROM MINERAL CRYSTAL INTO COLLOIDAL ADSORPTION ATMOSPHERE.—Since three successive crops may reduce the supply of exchangeable nutrients of the clay to 85 per cent of exhaustion, we are immediately confronted with the fact that continuous cropping on many experimental fields has gone forward for more than half a century without even approaching such a high degree of depletion of the exchangeable nutrients in the soil. How then is the supply on the exchange atmosphere of the clay maintained? Graham (1940), in his use of the colloidal hydrogen-clay in contact with pure minerals

TABLE 3. *Calcium available by root contact (pounds per acre six inches deep) and contained in normal crops.*

Crops	With contact exhaustion of surface calcium at			Content of normal crops Pounds
	100%	85%	50%	
Soybeans43	.36	.17	5.4 per ton forage
Oats	2.58	2.19	1.03	4.1 per 25 bu. grain and 1,200 lbs. straw
Rye (winter)	5.21	4.43	2.08	2.8 per 15 bu. grain and 1,000 lbs. straw
Bluegrass (Kentucky)	11.33	9.62	4.53	10.0 per ton forage
	(Column 1)	(Column 2)	(Column 3)	(Column 4)

of silt size, has demonstrated that the adsorbed hydrogen on the clay is active in exchanging itself for the cations of the mineral. This exchange serves to nourish plants (Graham, 1941). The silt fraction with its mineral store is then the supply from which that of the clay is replenished after depletion by plant growth.

ION MOVEMENT FROM SILT PARTICLES DIRECTLY TO PLANT IS POSSIBLE BUT SMALL.—That ions can be taken in some measure by the plants directly from mineral particles of silt size without the intervention of the clay has also been demonstrated by Graham (1941). Plants failed, however, to grow as well under such conditions as on the silt in the presence of other colloids less active than clay, and decidedly not as well as on the silt mixed with the colloidal clay. It was only when an acid clay was mixed with the minerals of silt size that the growth of the plants was most effective. Plants can then use the minerals directly and the silt size separates may serve, but their contribution is small. This may be a case of limitation strictly to surface contact area, since ionic movement from crystal to crystal does not seem so probable.

EXCHANGE CONCEPT CLARIFIES RELATION OF SOIL DEVELOPMENT TO CROP PRODUCTION.—Only in those soils, in which the mineral reserve is ample both as to the kinds and the amounts of necessary elements, will production be maintained for more than a three-year period of continuous cropping. Mineralogical studies of the silt fraction of the soil with its classification as dominantly quartz or "other-than-quartz" will contribute much to better understanding of the continued productivity of some of our lands. By knowing the extent to which the clay is exhausted of its nutrient cations, or the reciprocal, namely, the extent to which the clay has become saturated with hydrogen, and by knowing, in addition, the extent to which the reserve of mineral crystal nutrients in the silt fraction is exhausted, we can make some estimate of the degree of soil development and of the possibilities of crop production as to kind and quality. Such understanding of the soil in its practical significance is more easily obtained by aid of the concept of exchange between the colloidal clay and the root surface.

In the inorganic portion of the soil, then, the immediate supply of nutrients for plants would seem to

be on the colloidal clay in the adsorbed form. The "other-than-quartz" minerals of silt size would then seem to be the reserve supply for either direct or indirect use in the future, if not for part of the immediate growing season. The colloidal clay, then, aids through two steps in nourishing plants. In the first, through its root contact, it serves to deliver nutrients by cation exchange. In the second, it serves in connection with the mineral breakdown of the silt fraction of the soil. By means of this view of the soil and root behaviors mainly as contact and surface phenomena, we may visualize more clearly and interpret more simply the processes of plant nutrition, of depletion of soil fertility and others connected with crop production and soil maintenance.

SUMMARY

By means of some data giving the root surface per unit volume of soil and some giving the surface areas of colloidal clay, the calcium delivery to the crop through exchange phenomena was calculated. The calculations suggested that a crop gets more calcium than is present on only that clay surface in immediate root contact. The data suggested that exchangeable ions move from one clay particle to the next clay particle through several such layers.

Hydrogen movement from hydrogen clay into calcium clay and the reverse movement of calcium were demonstrated. Hydrogen clay contact with mineral crystals demonstrated similar exchange from the crystal to the clay colloid. Ionic movement from the mineral crystal to the root by direct contact failed to nourish the plants amply, yet the crystal in contact with the clay served effectively.

Thus in terms of these surface phenomena of the colloidal clay and the root, we may get a clearer concept of how the adsorbed nutrient supply of the clay is replenished from the mineral crystals of the soil. By means of this concept we can visualize more clearly the mechanism involved in plant nutrition, soil fertility depletion, and various aspects of crop production and soil maintenance.

THE INFLUENCE OF VOLCANIC ERUPTIONS UPON POST-PLEISTOCENE FOREST SUCCESSION IN CENTRAL OREGON¹

Henry P. Hansen

THE DISTRIBUTION and abundance of peat bogs in North America is largely determined by the boundaries of Pleistocene glaciation. The occurrence of innumerable lakes within the glaciated region is responsible for their great number, and sufficient precipitation over much of this region permits the maintenance of a constant lake level or water table in the bog. Apparently most of the environmental conditions have been at an optimum for hydrarch plant succession culminating in the formation of peat deposits. Climate is perhaps one of the chief ecologic factors concerned with the development and continued accumulation of peat and other types of pollen-bearing sediments. The proximity of the Pacific Ocean and the presence of the Coast Range, Olympic Mountains, and the Cascade Range, permit the existence of a great diversity of climates, and hence, many plant formations in the Pacific Northwest. All of Oregon, and most of Washington and Idaho lie south of the boundaries of Pleistocene continental glaciation, and, consequently, peat deposits and other types of sediments suitable for pollen analysis are not common over much of this vast region. Where the climate is not too dry, the absence of ponded water has inhibited the initiation of hydrarch plant succession and subsequent accumulation of peat. The greatest number of peat deposits is in the Puget Lowland of western Washington, which was glaciated and where the climate is favorable for maximum bog development. Peat deposition has also occurred in montane glacial lakes and along the Oregon Coast, where the erosion cycle of a submerged shoreline has resulted in the formation of many lakes (Hansen, 1941c). In the latter region, sand dune lakes also support various stages of hydrarch plant succession, but they are usually recent or of uncertain age. East of the Cascade Range in Oregon and Washington the few existent lakes are usually too alkaline to permit hydrarch succession, or fluctuating water levels do not encourage peat deposition. In other areas the mature topography with its efficient drainage prevents the existence of standing water and subsequent hydrarch plant succession. Tule swamps are rare, and those examined overlie shallow strata of black muck, unsuitable for pollen analysis.

LOCATION AND CHARACTERISTICS OF THE BOG.—The peat deposit of this study is located about 13 miles west of Bend, Oregon, in section 16 of T. 18 S., R. 10 E. on the Three Sisters quadrangle. The elevation of the bog is about 5,240 feet above sea level. The peat and other pollen-bearing sediments have accumulated in Tumalo Lake, a small lake that was apparently ponded by the terminal moraine of

a valley glacier in a tributary of Tumalo Creek. The latter empties into the Deschutes River a few miles north of Bend. The Pleistocene mountain glaciers in this region evidently reached lower elevations, but post-Pleistocene volcanic activity has largely obliterated the surface effects of glaciation. In recent years the lake level has been raised by an artificial dam on the moraine at the lower end of the lake. In the autumn of 1940, the lake was drained to remove peat for commercial purposes, and a complete profile was obtained where the surface had not been disturbed. The hydrarch plant succession had reached a sedge-meadow stage with an abundance of *Hypnum* moss before the lake level was raised artificially. This stage of plant succession is similar to that of a montane bog on the east slope of the Cascades in central Washington, where the climate is also the same (Hansen, 1939c). The area of the peat deposit is about 300 feet wide and 600 feet long. The adjacent valley slopes rise directly from the edge of the bog. Peat samples were obtained with a Swedish-type peat borer. The depth of the sediments in the area of sampling is 7 meters, and test borings made across the bog show that the bottom is flat most of its width. This suggests that the lake was ponded in a U-shaped valley of glacial origin.

Two layers of pumice are present in the peat profile, one at 4.5 and the other at 2.0 meters. The occurrence of the pumice strata is significant, because the change in the edaphic conditions due to the deposition of the pumice in this region evidently had a marked influence upon the forest succession as suggested by the pollen profiles. There are several possible sources of the pumice, there having been considerable volcanic activity in Cascade Range of Oregon during post-Pleistocene time. It is probable that the pumice had its origin from one of the following: Mount Mazama, about 80 miles to the south; Newberry Crater, about 25 miles to the southeast; and Devils Hill,² about 11 miles to the west of the peat deposit (Williams, 1935, 1941). The eruption of Mount Mazama, forming the caldera holding Crater Lake, occurred during the post-Pleistocene between 5,000 and 10,000 years ago (Williams, 1941). The pumice mantle from this eruption extends with diminishing thickness to the east and for a distance of about 100 miles to the north. The site of the sediments of this study is located within a zone where the pumice is from 1 foot to 6 inches thick. It seems probable that at least one of the pumice strata had its origin from Mount Mazama. Two peat deposits farther south in the vicinity of Crater Lake, that lie definitely upon Crater Lake pumice, are 2 meters deep as determined by the writer. Assuming that the rate of deposition has been about the same in both

^a Levels at which pumice occurs^b Number of *Abies* and *Pinus* pollen grains discarded, not computed in the percentages.^c Number of pollen grains, not computed in the percentages.

areas, it suggests that the pumice at 2 meters came from the Mount Mazama eruption. If 6,000 years have elapsed since its eruption, the rate of peat deposition has been consistent with that of other post-glacial bogs in the Pacific Northwest (Hansen, 1942a). Thus, the lower pumice stratum must have come from a much earlier eruption of Mount Mazama or some other volcano. The separation of the two layers by 2.5 meters of fine peat indicates that the first eruption may have occurred about 12,000 years ago. Post-Pleistocene peat profiles in the lower Willamette Valley of western Oregon contain a single layer of pumice, less than 2 meters from the present surface of the sediments (Hansen, 1942b). It is possible that this layer owes its origin to the same volcanic eruption as the upper stratum in the peat profile of this study.

In the preparation of the peat for microscopic study, the potassium hydrate method was used. From 150 to 200 pollen grains of significant species were identified from each level, except the lowest at 7 meters, where no pollen was present. The size-range method, which has been described in several recent papers, was used in separating the species of *Pinus* and *Abies* (Hansen, 1941a, 1941b, 1941c). In this study it should be noted that pollen listed as that of *Pinus monticola* probably includes some of *P. albicaulis* which is present near timberline. Also pollen listed as that of *P. ponderosa* may include small proportions of *P. albicaulis* and *P. lambertiana* due to a slight overlap of their size-ranges. In the firs, pollen identified as *Abies nobilis* may include some of *A. concolor*, although the small proportions of fir pollen present make this source of error negligible. The size-range method in the identification of fossil winged conifer pollen is shown to be feasible by the consistency of pollen profiles in certain peat profiles. In four peat profiles from Lower Klamath Lake of Oregon and California, the pollen profiles of each species of pine are similar in their major and significant trends (Hansen, 1942a). The separation of western yellow and western white pine is important because of the climatic indicator value of these species. The identification of lodgepole pine pollen is also essential, not for the interpretation of climatic trends, but rather for the recorded interruption of forest succession due to changes in edaphic conditions or other non-climatic environmental factors. It is particularly significant in this study. Pollen is abundant at most levels, with more than 1,000 pollen grains present on a single slide at many horizons. This is perhaps due to the fine type of sediments, which require a long period of time for their deposition, resulting in a concentration of pollen of many seasons in a small unit of thickness. The enormous quantity of pollen shed by the various species of pine is also a factor in the abundance of pollen present. Those species recorded by less than 1.5 per cent are listed in the table as 1 per cent.

FORESTS IN ADJACENT AREAS.—The terrain of the region surrounding the bog is extremely rugged with considerable relief. The divide of the Cascade Range

is about 15 miles to the west. The South Sister, reaching an elevation of 10,354 feet, rises about 13 miles to the northwest and supports large glaciers. Broken Top peak, about 10 miles to the northwest, also has glaciers, and there are many peaks within several miles that attain a height of over 6,000 feet. The elevation decreases to the east, with the less rugged regions lying at an altitude from 3,000 to 4,000 feet. This great relief permits the existence of several life zones within a few miles of the site of the sediments. The bog lies within the timbered Arid Transition area (Bailey, 1936). The rapid increase in elevation to the west causes this to grade into the Canadian which in turn grades into the Hudsonian zone at still higher altitudes. The Arctic-alpine zone occupies considerable areas on the upper slopes of the Three Sisters. At lower elevations to the east the timbered Arid Transition gives way to the timberless part of the same area, which in turn grades into the Upper Sonoran zone still farther to the east. Much of the timbered Transition is forested with western yellow pine (*Pinus ponderosa*), which forms a zone of varying width along the eastern flank of the Cascade Range in Oregon and Washington. This zone, however, is broken and discontinuous for a distance of about 100 miles from Crater Lake to Bend. Vast forests of lodgepole pine (*Pinus contorta*) occupy the pumice-covered areas that extend north and east of Crater Lake. Forest type maps (1936) show an almost uninterrupted belt of yellow pine east of the lodgepole pine forests where the pumice mantle is not so thick as farther to the west. North of Bend, the lodgepole pine zone tapers to nothing, and is practically absent for the last 100 miles to the Columbia River. This suggests that the prevalence of lodgepole pine in this region is due to the pumice mantle, and that the other ecological conditions are such as normally to support a forest of yellow pine over most or all of the timbered Arid Transition.

At some points the lower limits of the yellow pine zone grade into sparse forests of western juniper (*Juniperus occidentalis*), which occupy a considerable area in central Oregon. In other places the yellow pine forest gives way directly to the bunchgrass prairie. Near the upper boundaries of the yellow pine zone, sugar pine (*P. lambertiana*), Douglas fir (*Pseudotsuga taxifolia*), lowland white fir (*Abies grandis*), white fir (*A. concolor*), western red cedar (*Thuja plicata*), incense cedar (*Libocedrus decurrens*), and western larch (*Larix occidentalis*) may be found on favorable sites. Sudworth (1908) gives the southern limits of the range of western larch as the headwaters of Squaw Creek, 10 miles to the northeast of Tumalo Lake. A few specimens, however, were noted in the vicinity of the lake.

The most common species of conifers in the Canadian zone immediately above the Transition are western white pine (*P. monticola*), western hemlock (*Tsuga heterophylla*), Engelmann spruce (*Picea engelmanni*), noble fir (*Abies nobilis*), silver fir (*A. amabilis*), Douglas fir, lowland white fir, and lodgepole pine. In this zone lodgepole pine also occupies

the pumice-covered areas, or areas where fire has been to its advantage. Next to lodgepole, western white pine is perhaps the most abundant species in this zone. The Hudsonian zone is more sparsely forested than the Canadian, and the principal species are mountain hemlock (*Tsuga mertensiana*), white bark pine (*P. albicaulis*), alpine fir (*A. lasiocarpa*), and Alaska cedar (*Chamaecyparis nootkatensis*). The boundaries of these zones are irregular, the forests of each extending upward or downward beyond the general limits where conditions are favorable.

The peat deposit is located within a climatic province designated by Thornthwaite (1931), as being subhumid and microthermal, with adequate precipitation at all seasons. The climatic zones are narrow in this region, because of the steep slope of the Cascades. The precipitation increases at higher elevations to the west and decreases at lower altitudes to the east. The mean annual precipitation at Bend, 13 miles to the east and at an elevation of 3,629 feet, is 13.21 inches, and at Sisters, about 20 miles to the north at an elevation of 3,175 feet, it is 16.65 inches (Climatic Summary, U. S. D. A.). At Bend, about 27 per cent occurs during May to September inclusive, and at Sisters, about 21 per cent falls during the same period.

POST-PLEISTOCENE FOREST SUCCESSION. — The depth of the sediments suggests that they represent the greater part of postglacial time. The fineness of the sediments and the type of vegetation contributing to their deposition indicate that the rate of sedimentation was slow. The average depth of six post-Pleistocene peat deposits studied in eastern Washington and Oregon is 6 meters, which is slightly less than the 7-meter depth of the bog of this study. As previously stated, the eruption of Mount Mazama occurred not less than 5,000 nor more than 10,000 years ago. If the upper layer of pumice at 2 meters owes its origin to this eruption, then the age of the peat profile is perhaps 15,000 years. If the lower stratum at 4.5 meters represents this eruption, then the sediments had their origin somewhat later. The total depth of the sediments, however, suggests the former figure.

The forests recorded in the lowest pollen-bearing level at 6.75 meters consisted chiefly of western larch, lodgepole pine, western white pine, and western yellow pine. The first was apparently the most abundant, and contributed 33 per cent of the pollen (fig. 1). Lodgepole, western white, and western yellow pine are represented by 30, 14, and 14 per cent, respectively. It is probable that larch was predominant by a greater margin than is denoted by the pollen proportions, because this species does not shed nearly so much pollen as the pines, especially lodgepole. Larch pollen percentages decline rather abruptly from the lowest level upward, to show only 2 per cent at 5.75 meters. It is then recorded sporadically in low proportions to the surface. Larch is not recorded by its pollen to any great extent in Pacific Northwest bogs, even though they are located within

forests including appreciable proportions of this species (Hansen, 1939a, 1939c, 1940b, 1941e). The highest proportion present is 25 per cent in a bog near Spokane, Washington (Hansen, 1939b). In Wisconsin bogs, tamarack (*Larix laricina*) is only sparsely represented, even though it is the chief tree on bogs in their climax stage (Hansen, 1937, 1939d). Apparently the pollen of species of this genus is not well preserved in peat. The predominance of larch in the lower horizon is significant in that the bog lies near the southernmost limits of its geographic range in Oregon. The sporadic occurrence of its pollen in the upper part of the profile indicates that it was never abundant after its initial predominance. The proportions of larch pollen in the lower four levels suggests the occurrence of repeated fires prior to initial sedimentation. Larch has thick bark and is able to withstand successive severe fires that may destroy first the parent trees of other species, and then their seedlings. The lack of competition for light then permits it to flourish until other species are able to regain a foothold. If undisturbed by fire, these will eventually replace the larch (Sudworth, 1908; Larsen, 1929). Lodgepole pine may also increase in abundance after fire, but this is due to release of seed from the cones as a result of heat, rather than survival of the parent trees. Subsequent fire before seed-bearing age may completely eradicate this species.

The several species of pine show a general increase to 5.5 meters, with lodgepole pine becoming predominant (fig. 1). Yellow pine is then recorded as increasing abruptly to 44 per cent at 4.5 meters, white pine remains constant, and lodgepole pine decreases to 19 per cent. Most of this region is normally forested with a yellow pine climax, and it seems probable that the initial increase in this species depicts a warming and drying of the climate as the effects of recent glaciation were modified. Modification of the conditions left by the hypothetical fires may also have been a factor in its increase. Lodgepole pine shows a sharp increase from 19 per cent at 4.5 meters, whereas yellow pine declines to only 12 per cent at this level. White pine remains more or less constant. It is extremely significant that a stratum of pumice is present at 4.5 meters, indicating that a volcanic eruption occurred at this time, depositing a pumice mantle over this region. This apparently resulted in an increase in lodgepole pine due to the change in the edaphic conditions or possibly because of further fire. The depth of the pumice was probably not sufficient to kill the existing yellow pine forests outright. The changes in the edaphic conditions, however, may have been unfavorable for yellow pine seedlings, and lodgepole was thus able to thrive because of the absence of competition. The general constant trend in the pollen proportions of white and white bark pine during this interval suggests that they were unaffected by the pumice because of their existence at higher elevations to the west, where the pumice mantle is thinner or absent. Lodgepole pine is recorded as generally declining

from 1.25 to 2 meters, yellow pine shows a slight increase, and white and white bark pine continue their static trend. The increase in yellow pine suggests a partial return of this species as the pumiceous soil perhaps was gradually modified by climatic and biotic factors. Lodgepole is again indicated as increasing, less gradually than at first, upward from the 2-meter horizon. The occurrence of a second layer of pumice at this level records another volcanic eruption and deposition of volcanic material, with accompanying changes in edaphic conditions favorable

for lodgepole pine. Although it seems probable that the source of this pumice was the eruption of Mount Mazama, an increase in erosion may have washed the pumice into the lake from adjacent slopes. Erosion greater than normal may have resulted from deforestation by fire, which in itself would cause edaphic and biotic changes favorable for an increase in lodgepole pine. Lodgepole shows an increase upward to .75 meter, and then it declines slightly to the surface. Yellow pine is recorded as slightly declining from 2 meters for several levels upward, and then it remains constant to the surface. White pine also maintains its static trend to the top. The surface sediments record 50, 21, and 16 per cent for lodgepole, yellow, and white pine, respectively (fig. 1). It seems probable that lodgepole is over-represented because of its extensive existence windward to the site of the sediments. Conversely, yellow pine is under-represented because of its existence largely leeward to the bog.

Other coniferous species recorded by their pollen, either consistently or sporadically throughout the peat profile, are sugar pine, western and mountain hemlock, Douglas fir, Engelmann spruce, and lowland white, alpine, and noble fir. Mountain hemlock and noble fir are most abundantly and consistently represented. Sugar pine pollen is present in the lower levels, but is entirely absent in the upper 2 meters. Grass, Composite, and Chenopod pollen occurs sporadically in the profile, but these species were never extensive near the site of the sediments. Broadleaf trees including alder, birch, maple, and willow are sparsely represented. Sedge pollen is present at all horizons and shows a slight increase

in the upper levels as the sedge-meadow stage of hydrarch succession progressed (table).

CLIMATIC CONSIDERATIONS.—There seems to be little evidence for climatic trends in the pollen profiles of this study. The increase in yellow pine from the bottom to 1.5 meters may mark a drying and warming during the early postglacial, but its continued development was apparently interrupted by the deposition of the pumice mantle. Desiccation of postglacial climate is denoted by pollen profiles of other peat deposits east of the Cascades in Washington and Oregon. Sediments from Lower Klamath Lake record drying and warming by an increase in yellow pine to a maximum from the bottom to about halfway up in the profiles (Hansen, 1942a). This was followed by slightly cooler and moister conditions. A bog near Spokane, Washington, located in a yellow pine climax, records a sharp increase in grasses, Composites, and Chenopods, marking a hot, dry period during the middle third of the post-Pleistocene (Hansen, 1939b). In north central Washington, pollen profiles suggest a gradual drying to a maximum that has persisted to the present (Hansen, 1940b). In the lower Willamette Valley of western Oregon, three peat profiles record an influx of white oak (*Quercus garryana*) of considerable magnitude in the upper levels (Hansen, 1942b). The pollen profiles of this species and a decline in Sitka spruce (*Picea sitchensis*) and lowland white fir from the bottom upward is significant evidence for a dry period during the second half of the post-Pleistocene in the Willamette Valley. Pollen profiles of a peat deposit in the eastern foothills of the Coast Range in west central Oregon also provide evidence for warming and drying during this period (Hansen, 1941b). In other parts of the Pacific Northwest west of the Cascades, precipitation has probably not been a limiting factor in postglacial forest succession (Hansen, 1938, 1940a, 1941a). In a 7-meter profile of lake sediments in the Upper Sonoran life zone of east central Washington, the relative succession of grassland and forest suggests a warming of the climate during the postglacial to a degree persisting to the present (Hansen, 1941d).

Another source of evidence for a dry period during the middle third or latter half of postglacial time is the occurrence of artifacts underlying 6 to 8 feet of fibrous peat in Lower Klamath Lake (Cressman, 1940). The lake was drained in 1917, and wind and fire removed the fibrous peat, exposing an extensive artifact horizon. This signifies that the lake dried up sufficiently to permit early man to build his camp sites upon the exposed bed. A later increase in moisture resulted in inundation of the lake bed and the subsequent deposition of 6 feet of tule peat. Antevs (1940) estimates this period of desiccation to have occurred between 7,500 and 4,000 years ago. This dry period may have been synchronous with that indicated by the pollen profiles mentioned above. The occurrence of a postglacial dry period is further substantiated by the salinity of certain lakes in the Great Basin. The present salinity of these lakes is

too low to represent a continuous deposition of salts during the entire post-Pleistocene (Antevs, 1938). Apparently the lakes dried up, and their precipitated salts were removed by wind or buried. The present lakes were reborn in the freshened basins about 4,000 years ago. This is believed to have been synchronous with the reinundation of the Lower Klamath fossil lake bed. Another line of evidence for a dry period is that the remnants of most Pleistocene glaciers in the western mountains entirely disappeared during the postglacial, and the present glaciers were formed only a few thousand years ago (Matthes, 1939). Their wasting and rebirth are thought to have resulted from decreased precipitation followed by an increase in moisture. Pollen profiles in eastern North America also indicate a period of maximum warmth and dryness, succeeded by an increase in moisture and some cooling in recent time. The author hopes to show that all or most of these lines of evidence for a dry postglacial period are chronologically correlated.

SUMMARY

A montane peat deposit on the east slope of the Cascade Range in central Oregon records post-Pleistocene forest succession that was apparently influenced more by the deposition of pumice than by climate. At least two volcanic eruptions are evidenced by the presence of pumice strata in the peat profile.

There are four major trends of forest succession as interpreted from the pollen profiles. An initial predominance of western larch suggests the occurrence of repeated fire just prior to the origin of the sediments. When the effects of the hypothetical fires had been modified, lodgepole pine assumed predominance for a short time, only to be superseded by western yellow pine as the climate became warmer and dryer. Yellow pine never reached a maximum, however, because its trend was interrupted by a pumice fall that caused unfavorable edaphic conditions for its continued development. Lodgepole pine once again became predominant.

Lodgepole retained its predominance during the rest of the post-Pleistocene, but yellow pine gained slowly until another pumice fall interrupted its climax trend. Lodgepole pine made a less precipitate gain, but it attained the same proportion as it did after the first eruption. It is believed that the yellow pine forests which lie chiefly leeward to the bog in this region are under-represented by their pollen in the profile. The source of the pumice is not known with certainty, but it seems probable that at least one, probably the upper layer, came from the eruption of Mount Mazama between 5,000 and 10,000 years ago.

METABOLISM OF ORGANIC ACIDS IN EXCISED BARLEY ROOTS AS INFLUENCED BY TEMPERATURE, OXYGEN TENSION AND SALT CONCENTRATION ¹

Albert Ulrich

In a previous paper (Ulrich, 1941) data were reported on the relationship between cation and anion accumulation and organic acid metabolism in excised barley roots. The general conclusion was that when cations were absorbed in excess of anions from the external culture solution, the ionic balance in the root cells was adjusted by the formation of organic acids and that conversely, when anions were absorbed in excess of cations, the organic acid content of the roots decreased. In the present paper the effects of temperature, oxygen tension and salt concentration of the external culture solution upon the organic acid content of excised barley roots will be presented.

The technique employed for studying the metabolism of organic acids in excised barley roots has been reported (*loc. cit.*), and will be summarized only briefly. Under a carefully standardized procedure barley seeds were germinated and grown in darkness for five days and sixteen hours. At the end of this period, the excised barley roots were placed into the desired culture solution maintained at a definite temperature and constant oxygen tension (Ulrich, 1940). Following the removal of the roots after treatment in the culture solution, they were centrifuged to remove excess solution and stored at -18°C . until chemical analyses could be made on the expressed sap.

EFFECT OF TEMPERATURE ON ORGANIC ACID CONTENT OF EXCISED ROOTS.—The organic acid content of plants has generally been reported to be inversely related to changes in temperature (Bennet-Clark, 1933b; Wolf, 1931, 1938). Wolf (1931) considers that the rate of formation of organic acids is decreased at low temperatures, but that at the same time their rate of decomposition is decreased to an even greater extent. At higher temperatures the rate of decomposition is increased faster than the rate of formation and consequently the quantity of organic acids decreases. Bennet-Clark (1933b) believes the formation of organic acids has the following schematic relationship, and accordingly should follow the Le Chatelier principle.

This principle was apparently satisfied, when Bennet-Clark showed that the organic acids previously accumulated were soon lost from detached leaves of *Sedum praealtum* kept in darkness at 27°C . The low acid content was maintained until the leaves were

¹ Received for publication October 24, 1941.

Appreciation is expressed to Professor D. R. Hoagland for counsel received during the course of the investigation.

Assistance in clerical work was furnished by the personnel of the Works Projects Administration Official Project No. 65-1-08-91-B-10.

transferred to a lower temperature (3°C .), when a gain in acids was recorded. Similar leaves kept initially at 3°C . showed a gain which was followed by a loss in acids after transferring to a temperature of 27°C .

In order to determine if excised barley roots behaved in a similar manner, sets of roots were placed for eight hours in 0.0005 M CaSO_4 solution maintained at 5° , 15° , 25° , or 35°C . (previously brought into equilibrium with air by aeration at the desired temperature). The results are recorded in figure 1.

Fig. 1. Effects of temperature on the metabolic activity of excised barley roots in 0.0005 M CaSO_4 solution for eight hours. CO_2 and O_2 are given in cubic centimeters for 100 grams of excised roots. R.Q.— CO_2/O_2 . Sugar—total sugars expressed as grams glucose per liter of expressed sap. The following are given as milliequivalents per liter of sap: O.A.—total non-volatile organic acids; NH_3 + amide—N.—ammonia plus amide nitrogen. pH values were determined on expressed sap.

The total organic acid content of roots in the 0.0005 M CaSO_4 solution (36.5, 39.8, 40.7, 42.8 meq. per liter at 5° , 15° , 25° , and 35°C . respectively) changed only slightly even though the total respiration, as shown by the carbon dioxide evolved and by the oxygen absorbed, was approximately doubled for each 10°C . rise in temperature. With the exception of significant decreases in sugar content, other factors which might have been influenced by temperature showed little or no change. The changes in the hydrogen ion activity and in amide plus ammonia nitrogen concentrations were insignificant, although the latter tended to increase slightly from 15° to 35°C . Even though significant decreases in total sugar content occurred at all temperatures studied, there remained a large supply of sugar in all roots at the end

of the experiment, so that a deficiency of sugar could not have limited organic acid formation. The relatively large decrease in respiratory quotient at 5°C. is not to be considered significant, since the errors in setting the zero point in the mercury manometer are relatively great when measuring small quantities of oxygen. These errors do not occur in the carbon dioxide determinations, and these values may, therefore, be used for comparative purposes.

EFFECT OF TIME AND TEMPERATURE ON ORGANIC ACID FORMATION.—Using the same culture solution as in the previous study (0.0005 M CaSO_4), and the temperatures of 5°, 15°, and 25°C., the observation periods were extended from eight hours to a maximum of fifty-six hours (fig. 2-4). For each time interval and temperature a separate set of roots was taken. The results (including buffer curves not shown here) indicate that if there is a time element involved in the formation of organic acids at temperatures ranging from 15° to 25°C., it must be beyond 56 hours. At 5°C. there is a small increase in organic

Fig. 2. Effects of time on the metabolic activity of excised barley roots in 0.0005 M CaSO_4 solution maintained at 5.0°C. (For explanation of values see figure 1.)

acids at the end of 56 hours, which, however, may not be significant. In the light of the data previously presented (Ulrich, 1941) the extent of this organic acid increase could be intimately related to the hydrogen ion deficit (pH increase) induced by metabolic changes at the lower temperature.

Other noteworthy points arising in the time-temperature study may be illustrated by the results of the experiments at 25°C. for the time intervals of 8, 20, 32, and 56 hours (fig. 4). The respiratory activity (fig. 5) decreased gradually for the first 32 hours and then increased slightly for the 44- and 56-hour periods. During the 56 hours (fig. 4) the total sugar content decreased from an average value of 10.6 grams to 1.20 grams per liter of sap, while

the organic acid content remained practically constant. If there were a dynamic equilibrium between total sugars and organic acids in the barley roots as postulated by Bennet-Clark (1933b) for succulents it would be expected that the organic acids might likewise be depleted. Under the present conditions a

Fig. 3. Effects of time on the metabolic activity of excised barley roots in 0.0005 M CaSO_4 solution maintained at 15.0°C. (For explanation of values see figure 1.)

decrease in the organic acids failed to materialize except when the root cells had been depleted of total sugar for some time. Then the organic acids decreased; the inference was drawn that they were utilized in respiration (Ulrich, 1941). Furthermore, the required relationship of organic acids to the rate of CO_2 output (high CO_2 production, low organic

Fig. 4. Effects of time on the metabolic activity of excised barley roots in 0.0005 M CaSO_4 solution maintained at 25.0°C. (For explanation of values see figure 1.)

acids, and *vice versa*) as observed by Bennet-Clark in *Crassula lactea* was not apparent with barley roots, since under the present experimental conditions there were no ionic changes requiring the formation or loss of organic acids as would occur when roots absorb from salt solutions cations in excess of anions (e.g., K_2SO_4 , KH_2PO_4 , K citrate, $KHCO_3$) or anions in excess of cations ($CaBr_2$, and under certain conditions, KBr). The results of Thoday and Jones (1939) with *Kleinia articulata* likewise are not explained by Bennet-Clark's hypothesis, since they failed to find the required fluctuations in respiration.

Fig. 5. Oxygen absorbed and CO_2 evolved by 100 gm. of excised barley roots in 0.0005 M $CaSO_4$ solution maintained at $25^\circ C$.

The increase in pH at the 32- and 56-hour intervals was most likely the result of an increase in ammonia in the ammonia plus amide fraction (fig. 4). This was not accompanied by a corresponding increase in organic acids as would be expected from Ruhland and Wetzel's (1926, 1927) theory, according to which the organic acids are thought to be formed from oxidative deamination of amino acids. The failure of organic acid formation is also not in agreement with the theory proposed here that the acids are produced from carbohydrates as a result of a tendency towards increase of pH within the root cells. However, this failure to form acids, according to the latter hypothesis, may be due to the very low sugar content of the cells at the time of the pH change. This contention is supported by evidence of the loss in organic acids in the 56-hour KBr treated roots in which the total sugars were at a minimum (Ulrich, 1941, fig. 5).

Another point of interest is the effect of potassium bromide on respiration. At all temperatures except $5^\circ C$. the respiration is significantly higher in a solution of KBr (*loc. cit.*, fig. 3) from which active salt absorption occurs than in a $CaSO_4$ solution (fig. 1) from which few ions are absorbed. If the total respiration is considered, this same relationship holds true for the time studies except in the 56-hour period. Here in the KBr set (*loc. cit.*, fig. 5) the sugar decreased more than in the roots in the calcium sulfate solution (fig. 4), so that for this time interval the latter roots respired in excess of those in the potassium bromide solution. The higher initial respira-

tory activity of potassium bromide treated roots may be associated with effects on metabolism through the absorption of certain potassium salts. Steward and Preston (1941) have shown in experiments on potato discs that increased protein metabolism accompanied increased respiration, but so far protein metabolism has not been found to be a conspicuous feature in the case of roots for the limited time periods of the experiments.

RELATION OF OXYGEN TENSION AND SALT SOLUTIONS TO ORGANIC ACID FORMATION.—The necessity for maintaining the proper oxygen tensions in actively absorbing tissues was recognized by Steward (1932) with potato discs, and more recently by Hoagland and Broyer (1936) with excised barley roots. The possibility that oxygen tension might influence the organic acid content of succulents was considered during Pfeffer's time to be related to the morphological structure of such plants. Gaseous interchange was thought to be difficult, and it was therefore, considered that succulents, particularly the more fleshy types, would conserve their CO_2 at night by forming organic acids; on the following day these would be decomposed by light to make CO_2 available for photosynthesis. In this connection Warburg (1886) and subsequently Astruc (1903) and others, found that increased oxygen tensions increased the organic acid content of succulents either in the light or dark, while the converse was true for low oxygen tensions. The work of Richards (1915) on *Opuntia versicolor* contradicted this general conclusion. Since all these workers used the direct titration method to determine organic acids, their results are open to question. More recently Bendrat (1929) found with *Sempervivum glaucum* that in the absence of oxygen (vaselined leaves) there was no change in total acids, although there was a decrease in titratable acidity (method used by Warburg). Wolf (1931) repeated this work by placing leaves in a vessel which was then exhausted and refilled with hydrogen several times. He ascertained from the total organic acid content that in some cases acidification during the night was inhibited completely, while in others the inhibition was partial, thus verifying Warburg's earlier work.

In the present investigation the circulating system adopted for the study of respiration in excised barley roots was readily adaptable to investigating the effect of various oxygen tensions upon root metabolism, and upon the respiratory quotient (Ulrich, 1940). After a given oxygen-nitrogen mixture had been introduced into the apparatus, the oxygen content was maintained automatically at a constant value by the oxygen generator. In this manner one of the major difficulties arising in oxygen tension studies with closed systems was entirely eliminated. The results from experiments with excised roots held for eight hours at $25^\circ C$. and using various oxygen tensions and salt solutions are given in table 1.

In the series of experiments with 0.0005 M $CaSO_4$ solution and different oxygen tensions (table 1) the effect of oxygen tensions on metabolism in certain

aspects is noteworthy. The excised roots subjected to pure nitrogen (introduced into the circulating system by passing through pyrogallol; the oxygen generator was not in operation) showed the greatest change. The quantity of CO₂ evolved was still appreciable, and may have arisen in part from the residual oxygen not entirely removed from the roots at the start of the experiment, but probably in the main from anaerobic respiration. It is interesting to observe the large loss in total organic acids and sugar content. Since the roots held under an anaerobic condition during the eight-hour period were undoubtedly injured, part of these losses may have been caused by a direct loss of solutes, as indicated by turbidity of the final culture solution and by significant loss in root weight. While these changes were taking place, the combined ammonia and amide content was reduced slightly. This diminution may be associated with root injury or may be reconciled with the generally accepted viewpoint that oxygen is necessary for the formation of amides (Onslow, 1931; Chibnall, 1939), assuming here that the ammonia determined represented labile amides.

When excised roots were placed in 3.2 per cent oxygen, the reduction in respiration was significant. The low oxygen pressure resulted in an increase of the respiratory quotient, so that it was significantly greater than one. In spite of the low oxygen tension, the organic acid content was not lowered signifi-

cantly, indicating that extreme oxygen deficiencies must occur before appreciable amounts of these compounds are lost. The sugar loss was not as great as in pure nitrogen or in air. The ammonia + amide content was not greatly influenced, although the quantity of these constituents was lower than in the aerated roots.

An increase in oxygen content from 20 to 87.9 per cent did not alter the results significantly, but there was an increase in respiratory activity which might be attributable to the higher oxygen tension. There is no great oxygen deficiency in air, otherwise the respiratory quotient would be greater than one. The organic acid content, as before, was not influenced. Neither were the ammonia + amide and sugar contents. The pH value (5.28) was approximately that of the original roots.

The results of experiments conducted with 0.005 M KBr + 0.0005 M CaSO₄ (table 1) were practically identical with those of the 0.0005 M CaSO₄ solution. The respiratory quotients at the low oxygen tensions, 3.8 to 4.7 per cent, were again greater than one, the final sugar contents higher, and the ammonia + amide content depressed. The organic acid contents as before were not influenced by oxygen tensions as low as 3.8 per cent or as high as 85 per cent. At the lower oxygen tensions the respiratory activity along with absorption of KBr was greatly reduced. The general relationship between excess ca-

tion over anion absorption and organic acid formation held true even at the 3.8 per cent oxygen tension. At the 85 per cent oxygen tension there was no influence either on absorption of salt or on respiration over that of 20 per cent oxygen, but there was, as in the 0.0005 M CaSO_4 series, a lowering of the pH to 5.33.

In the oxygen tension study the possibility was considered that the absorption of nitrates might contribute to the oxygen supply necessary for respiration. The results in table 1 indicate that at 3.5 per

sulted in the formation of 8.6 milliequivalents per liter of organic acid.

In the 0.005 M KBr treated roots the milliequivalents of organic acids formed (7.2) approximated those of the excess cations absorbed (7.0), while, for roots placed in 0.025 M KBr solution, the cation excess was reduced to 5.1 milliequivalents per liter and 9.6 milliequivalents per liter of organic acids were formed. The ionic intake from the latter concentration as compared with 0.005 M concentration was almost doubled for the cations while the intake of anions was more than doubled. This increased absorption was not accompanied by a corresponding change in respiration. The actual increase in respiration was so slight that it is probably not significant. From this it may be inferred that the energy required for salt absorption was very small as compared to the total liberated in metabolism. The initial increase in respiration for the 0.001 M KBr solution was perhaps caused by a specific stimulation of metabolism by potassium bromide, but as more potassium bromide was absorbed, the initial influence on respiration diminished. The final concentrations of total sugar in the roots from the different KBr solutions were below those in the roots from the 0.0005 M CaSO_4 solution, although the differences may not be significant. The ammonia + amide content of the sap was not influenced significantly.

In the calcium bromide concentration study (fig. 7) the respiration of roots in culture solutions containing initially 0.0005 M CaBr_2 and 0.001 M CaBr_2 increased in comparison to those in 0.0005 M CaSO_4 solution. Decreases occurred in the 0.0025 M and the 0.0125 M solutions until in the latter salt concentration the oxygen absorbed by the roots was about equal to that taken up by those in the 0.0005 M CaSO_4 solution, while the carbon dioxide evolved was still significantly greater than in the absence of calcium bromide. The final sugar content in all the calcium bromide treated roots was significantly higher than in the roots treated with potassium bromide (compare fig. 7 with fig. 6) even though the CO_2 evolved in all cases except that of the 0.025 M solutions was approximately the same. Evidently, there is a fundamental difference in the metabolic products formed during the two salt treatments. Such a possibility was disclosed by Steward and Preston (1940) with potato discs in which potassium salts promoted protein formation in contrast with calcium salts. Another point of interest concerning calcium bromide absorption by barley roots is the reduction of the organic acids to minimum values (fig. 7). As is shown by the respiratory quotients, which are in these instances greater than one, this tendency is to release a considerable quantity of carbon as carbon dioxide which remained stored in the form of organic acids in the potassium bromide treated roots.

The relationship between cation and anion absorption from calcium bromide solutions merits particular attention. As far as could be ascertained from analyses of the external culture solution, there were no significant changes in the calcium content. How-

Fig. 6. Effects of potassium bromide concentration on the metabolic activity of excised barley roots maintained at 25.0°C. for eight hours. (K and Br values given as milliequivalents per liter of expressed sap. Other values as in figure 1.)

cent oxygen tension, there was an appreciable absorption of nitrate without great enhancement of respiration (compare with the similar KBr treatment given in table 1). The formation of organic acids was inhibited slightly at the lower oxygen tension, although the decrease may not be significant. In contrast with these results, the KNO_3 treatment with air increased respiration, the formation of organic acids and the use of sugar. Part of the oxygen for metabolism evidently was derived from the nitrates, since an increase in organic acids occurred without appreciably changing the respiratory quotient.

INFLUENCE OF SALT CONCENTRATION ON RESPIRATION AND FORMATION OF ORGANIC ACIDS.—Two salts, potassium bromide and calcium bromide, were used to study the influence of salt concentrations on respiration and the formation of organic acids. The results given in figures 6 and 7 indicate that initial concentrations of potassium bromide as low as 0.001 M have an effect on respiration almost as large as that of a 0.005 M solution (fig. 6). The quantity of cations absorbed from the 0.001 M KBr solution was approximately two-thirds, and the anion absorption was less than one-half of that in the 0.005 M KBr treated roots. The excess cation over anion absorbed equaled 10.5 milliequivalents per liter, and this re-

ever, the anion absorption was significant as shown by analyses of both the culture solution and the expressed sap. If the quantity of anions absorbed from the calcium bromide solution is contrasted with that absorbed from the potassium bromide solution, it will be found that the amounts in the respective saps are quite different. The quantity of anion absorbed from the potassium bromide solution increased with its external concentration, while the amount absorbed from calcium bromide solution remained nearly constant. This suggests some factor in the absorption mechanism which limits the intake of anions unaccompanied by cations. Perhaps this limitation is related to the extent of the organic acid anion decomposition, since the data in figure 7 indicate that the value for organic acids cannot be reduced under the present conditions below a certain minimum (33.2 to 40.2 meq.) in the presence of an ample supply of sugar. If the organic acid content of the original root material had been higher, it is possible that the anion absorption would have been greater. However, in the roots grown in the greenhouse by Hoagland and Broyer, in which the organic acid content is usually greater than in the roots grown in the dark by the present technique, the same relations exist between absorption of Br from KBr and CaBr₂. Possibly the rapid inward movement of K ions, as contrasted with Ca ions, accelerates the absorption of Br. This is a point requiring further investigation.

The data on absorption from calcium bromide solutions which show the effect on the pH of the expressed sap are of interest. The pH reaches a maximum value of 5.53 to 5.54 in all cases except in that of the 0.0005 M CaBr₂ solution for which it is 5.44. On the assumption that organic acids disappear when the plant cell tends to become more acid, the excess anion absorption should cause an increased acidity of the expressed sap. However, when it is considered that the dissociation constants of organic acids vary, it is possible that the acids that disappear or are reformed are those with high dissociation constants and consequently the acids that remain may actually lower the hydrogen ion concentration.

DISCUSSION.—The failure to influence the organic acid content of the excised barley roots by changes in temperature or oxygen tension is readily understandable from the viewpoint of the function of the acids in maintaining the acid-base balance of the cell sap. Neither changes in temperature from 5° to 35°C. or oxygen tensions of 3.2 to 88 per cent under the conditions of the experiments were influential in affecting the hydrogen ion concentration of the excised roots, and, consequently, there was no change in their organic acid content. The loss of organic acids occurring in an atmosphere of pure nitrogen may have been caused either by diffusion from injured cells or the counteraction of an increasing hydrogen ion activity.

The significant though relatively small increase in pH of expressed sap resulting from the calcium bromide treatment requires further consideration. According to the hypothesis here proposed, the ex-

cess anion absorption should effect a decrease in pH, which is in part counteracted by the decomposition of the organic acid anions, thus leaving the base in equilibrium with the absorbed bromide ions. With calcium bromide another factor may be involved in stabilizing the pH of the cell sap, namely, the decomposition of specific organic acid anions. If the organic acids having the highest dissociation constants were decomposed first, the remaining acids with lower degrees of dissociation would then tend to increase the pH. Analyses of the individual organic acids would be interesting from this standpoint.

Fig. 7. Effects of calcium bromide concentration on the metabolic activity of excised barley roots maintained at 25.0°C. for eight hours. (For explanation of values see figures 1 and 6.)

It would be of interest to reinvestigate the influence of temperature, oxygen tension and light on the organic acids of plants from the viewpoint of the acid-base hypothesis presented in this paper. In such an investigation the influence of secondary factors should not be overlooked. A case in point is Wolf's (1931) observation that during the day, either in the light or dark, the decrease in organic acid content of leaves of *Sempervivum glaucum* and *Bryophyllum calycinum* is greatly inhibited by a gaseous environment high in carbon dioxide. At first glance this seemingly would cause a decrease in pH and therefore a decrease in organic acids, but Fife and Framp-ton (1935) have shown with sugar beet leaves, that carbon dioxide increases their ammonia content, and according to the acid-base hypothesis here proposed, organic acids would be formed when carbohydrates are available. Another field which might be investigated profitably from the present point of view is suggested by the conflict in the ideas of the Leipzig school and those of Bennet-Clark and of Vickery, *et al.*, regarding the origin of the organic acids. The views of the latter, as well as the present findings with excised barley roots, suggest that the organic acids arise from carbohydrates and not from amino acid decomposition as proposed by Ruhland and

Wetzel (1926). Perhaps the ammonia determined by the Leipzig workers was derived from labile amides, thus giving a false correlation of organic acid formation with ammonia. However, if there were an actual increase of ammonia under their conditions, then an increase in organic acids may have occurred to maintain the acid-base balance of their plants, assuming, of course, an adequate supply of carbohydrates.

The evidence presented here considers one function of organic acids to be the maintenance of the acid-base balance in the buffer system of the plant cells. This may not be their sole function as is amply indicated in the literature (Bennet-Clark, 1933a, b, c; Chibnall, 1939; Ruhland and Wolf, 1936; Vickery and Pucher, 1940). The organic acids may be involved in the respiratory cycle or even in photosynthesis. They may serve as precursors in the formation of amino acids or amides. In the absence of an adequate supply of carbohydrates they may act as a temporary source of energy. The present data indicate that when the organic acids serve to maintain the acid-base balance in the cells, the respiratory cycle is affected, judging by the accompanying changes in the respiratory quotient. When the organic acids disappear in the excised barley roots during excess anion absorption, the respiratory quotient increases, and, conversely, when cations are absorbed in excess of anions, the respiratory quotient decreases. The source of these acids must be dependent upon sugars either directly or indirectly, since the acids fail to form in the absence of avail-

able sugar, even though there are pronounced changes in the pH of the expressed sap.

SUMMARY

The total non-volatile organic acid content of excised barley roots containing an ample supply of available sugar remained constant unless a change in the ionic balance took place within the roots. When roots absorbed an excess of anions over cations, organic acids disappeared. Conversely, when cations were absorbed in excess of anions, organic acids were formed. The respiratory quotients reflected these organic acid changes by increasing as the acids disappeared and decreasing when they were formed.

Although the formation of organic acids in barley roots was dependent upon the presence of sugars, the acids were not in a dynamic equilibrium with them, since large decreases in total sugars failed to decrease the acid content of the roots except when the sugars had attained very low concentrations.

The failure to affect the total organic acid content of the excised roots by temperature or oxygen tension changes was attributed to the lack of influence of these factors on the ionic balance of the root cells.

There was no evidence to support the contention that the organic acids arose primarily from the oxidative deamination of amino acids. The indirect evidence indicates that the acids were derived from carbohydrates. ✓

ADDITIONAL STUDIES REGARDING THE CATION ABSORPTION MECHANISM OF PLANTS IN SOIL¹

R. Overstreet, T. C. Broyer, T. L. Isaacs, and C. C. Delwiche

NUMEROUS INVESTIGATIONS bear witness to the fact that the absorption of inorganic ions normally present in the soil is essentially concerned with the physiology of the living root system. (For reviews of this subject see Hoagland, 1936; *Annual Reviews of Biochemistry*, 1932-; Hoagland and Broyer, 1936.) Such information, gained from studies of nutrient solutions, is of great interest to practical agriculture; however, a major problem in the growing of crops in the field is presented by the fact that the mere presence in the soil of an ion does not necessarily insure its availability to the plant. The nutrient cations in the soil are for the most part adsorbed on the surfaces of colloidal particles. Their release from the particles must occur in accordance with the laws of colloidal chemistry. For this reason a careful study of the mechanism by which the plant root effects this release would seem to be of great practical as well as theoretical importance. This paper purports to deal with certain aspects of this problem.

STUDIES WITH SOLUTION CULTURES.—Valuable information relative to the mineral requirements of plants has been obtained with the use of specially prepared nutrient solutions. Moreover, with this technique, the rates of absorption of ions from solutions by roots have been determined and numerous factors affecting the rates have been investigated (Hoagland and Broyer, 1936; Broyer and Overstreet, 1940).

Owing to the fact that with all suspensions we have to deal with an intermicellar as well as a micellar region, the solution culture studies constitute a reasonable starting point for the study of ion absorption from colloidal clay suspensions.

The present experiments are largely restricted to the investigation of the absorption of potassium by "low-salt"² barley roots. This ion, when present in solution cultures in association with monovalent

anions such as chloride, bromide and bicarbonate, is perhaps the one most rapidly absorbed by the experimental material. The rate of absorption is dependent within somewhat narrow limits on the concentration of potassium at the root surface. This fact will be evident from the following experiment.

Fig. 1. Rate of potassium absorption by excised barley roots as influenced by the concentration of potassium in the culture medium. Segments from the actively growing regions of barley roots were exposed for twelve minutes to culture media of concentrations from 1 to 8 milliequivalents per liter of total potassium as KCl. Radioactive K was employed as an indicator of the potassium absorbed.

From three-week-old barley roots, grown according to the method of Hoagland and Broyer (1936), unbranched segments 1 cm. in length were selected from regions within 4 cm. of the root tip. The mean diameter of the segments as measured with a micrometer was found to be 0.059 ± 0.003 cm. Samples comprising 120 segments each were exposed to flowing culture solutions containing radioactive potassium as KCl. At the conclusion of the absorption period (twelve minutes), the samples were ashed and the K absorbed determined by counting the ash with the Geiger-Müller counter. The mean rate of potassium absorption per unit root surface was calculated for the twelve-minute period, the approximate surface having been calculated from the measured diameter and length of the segments. The variation of absorption rate with concentration is given in figure 1. As may be seen from the graph, the absorption rate above a normality of 0.005 is evidently independent of concentration. Between the normalities of 0.005 and zero the rate diminishes rapidly. The maximum rate of potassium absorption was approxi-

¹ Received for publication October 27, 1941.

Technical assistance in the preparation of this publication was furnished by the personnel of the Works Progress Administration Official Project No. 465-03-3-587-B-10.

The authors desire to express their appreciation to Professors D. R. Hoagland and H. Jenny for their kind suggestions in connection with this problem. We are indebted to the Radiation Laboratory of the University of California for the radioactive potassium.

² The term "low-salt" implies that the plants during their growth period were limited with respect to their supply of essential nutrient salts (see Hoagland and Broyer, 1936). Roots of this type are also high in carbohydrate.

mately 7.8×10^{-7} milliequivalents per second per cm^2 . Since the fresh weight of 120 segments was found to be 0.365 gm., this rate is equivalent to 1.71 M.E. potassium per hour per 100 gm. fresh roots, which is a much higher rate than that usually observed for the whole root system (about 0.5 M.E. potassium per hour per 100 gm. fresh roots). Similar results have been reported by Prevot and Steward (1936).

It is of interest to compare the rate of potassium absorption per unit surface with the rate at which

Fig. 2. Comparison of the amounts of carbon dioxide liberated from and potassium absorbed by excised barley roots with time. Composite samples of barley roots were exposed for time periods of from one to five hours to colloidal K-bentonite suspensions, continuously aerated with a stream of CO_2 -free air.

the potassium ions collide with the surface. An approximate value for the number of collisions per unit time per unit surface may be calculated from the perfect gas laws. On the basis of this calculation, the value for a normality of 0.005 is approximately 10^{21} hits per second per cm^2 . When this value is compared with the corresponding absorption rate of 4.7×10^{14} ions per second per cm^2 , it becomes apparent that only about 10^{-5} per cent of the potassium ions striking the root surface are absorbed at this concentration.

STUDIES WITH CLAY SUSPENSIONS.—As has been discussed elsewhere (Overstreet and Jenny, 1939) all experimental evidence points to the fact that the composition of the intermicellar liquid in a clay suspension is not measurably different from that of the filtrate or centrifugate. When a suspension of a freshly electrolyzed hydrogen bentonite is titrated with KOH or NaOH to pH 7, potassium or sodium clay suspensions are obtained that yield filtrates very nearly devoid of electrolytes. For example, the filtrate from a 1.5 per cent potassium bentonite suspension (10 M.E. K per liter) prepared in this way was found to have a pH value of 7.3 (0.5×10^{-7} molal $[\text{H}^+]$). Thus the potassium concentration in the intermicellar liquid must have been of the order of 10^{-7} molal. On the basis of the data of figure 1, one would expect that accumulation of K by roots from such a solution would be extremely slow, even though the concentration of the solution

were constantly maintained. However, in apparent contradiction to this reasoning, barley roots readily absorb potassium or sodium from the homionic clay suspensions. With suspensions containing 1–5 M.E. per liter of adsorbed K the rate of K absorption by the plant has been found to be 25 to 50 per cent of that from comparable salt solutions. In the case of sodium clay suspensions in this concentration range, the absorption may even be greater than from the corresponding salt solutions (compare Overstreet and Jenny, 1939).

A number of explanations of this perplexing phenomenon have been proposed (Comber, 1922; Breazeale, 1923; Truog, 1927; Jenny and Overstreet, 1938). In the present instance we shall concern ourselves with the two most plausible explanations. The first of these involves the carbonic acid which is excreted by the roots during respiration. The second is based on the contact mechanism proposed by Jenny and Overstreet (1938).

The CO_2 hypothesis.—Barley roots continuously evolve CO_2 during ion absorption. The processes occurring within the plant requisite for active electrolyte accumulation (for example, the oxidation of sugars to organic acids and CO_2) invariably result in the excretion of carbonic acid. This fact is made clear from the following absorption-time curve for barley roots in K-bentonite suspensions (fig. 2). In obtaining each point on the curve, 5 gm. of excised barley roots were immersed in 300 ml. of a 1.45 per cent K-bentonite suspension which contained 10 M.E. K per liter. During the absorption period the suspension was aerated with CO_2 -free air. The outgoing air was led through a NaOH tower for the purpose of absorbing the evolved CO_2 . At the conclusion of each absorption period both the NaOH from the tower and the suspension were analyzed for CO_2 by means of the Warburg manometric method. The roots were washed, ashed and analyzed for K by means of the cobalti-nitrite method. The results were compared with K analyses on the original root material. The net potassium absorption and the total carbonic acid liberation were expressed as millimols per 100 gm. fresh roots. Inspection of the figure reveals that the K absorption and CO_2 liberation are nearly straight line functions of the time. As may be calculated from the graph, 1.8 millimols of CO_2 were given off by the roots for each millimol of potassium absorbed. This result is in harmony with previous experiments with clay suspensions wherein it has been observed that 1–2 millimols CO_2 were respired per millimol of K absorbed.

Inasmuch as the excretion of H_2CO_3 invariably accompanies the accumulation of ions by roots, it has seemed reasonable to many investigators to assume that the initial step in ion absorption by roots from clay suspensions is the release of ions adsorbed on the clay particles to the intermicellar liquid by an exchange for the hydrogen of carbonic acid. For the case of a potassium clay this process may be indicated as follows:

The second step in the accumulation process is, according to one view, the absorption of K^+ and HCO_3^- as ion pairs from the intermicellar liquid. However, appreciable accumulation by roots of HCO_3^- , as such, has never been demonstrated. In a recent study using radioactive carbon, Overstreet, Ruben and Broyer (1940) found that in the case of a culture solution of 0.001N $KHCO_3$, a small fraction of the HCO_3^- was apparently reduced by the roots with the formation in the tissue of compounds of high molecular weight. An extremely small fraction of the HCO_3^- was found unchanged within the root system. Moreover, it was found that the maximum number of equivalents of HCO_3^- utilized and retained in various carbon forms by the root system was far less than the number of equivalents of K^+ absorbed. This result is supplemented by absorption studies carried out in this laboratory (compare Ulrich, 1941) wherein a complete ionic balance is obtained on the culture solution and on the root sap following a period of active electrolyte absorption by the roots. The results of these studies indicate that an excess accumulation of cations over anions is compensated in the culture solution by hydrogen ions or other ions derived from roots (*e.g.* Ca) and in the root system by organic acid anions. The extension of this type of study to colloidal clay suspensions is embodied in the following experiment.

Five samples of "low-salt" excised barley roots (approximately 100 gm. fresh weight) were each immersed in 3,000 ml. of culture medium. The media comprised three salt solutions and two K-bentonite suspensions. The culture media were continuously aerated with a stream of CO_2 -free air for a period of five hours. The respired CO_2 was collected as before in NaOH towers. At the conclusion of the absorption period, the roots were thoroughly washed, weighed and frozen. The sap was then expressed from the roots by means of an hydraulic press. The press-cakes were dried at $80^\circ C.$ and weighed. The expressed saps were analyzed for Ca, Mg, K, Na, Br, SO_4 , PO_4 , Cl and organic acids. The results of the chemical analyses were expressed in terms of milliequivalents in the total sap from 100 gm. of fresh roots. On this basis it was found that the roots from the distilled water control contained 0.42 M.E. Ca^{++} , 0.19 M.E. Mg^{++} , 1.915 M.E. K^+ , 0.45 M.E. Na^+ , 0.00 M.E. Br, 0.45 M.E. SO_4^{--} , 0.43 M.E. PO_4^{--} , 0.06

M.E. Cl^- , and 3.26 M.E. organic acids.³ The respiration of 100 gm. of the control roots was 3.08 millimols CO_2 . The respiration and net gains or losses of the various ions as compared with the composition of the control roots are given for each sample in table 1.

The column denoted " Δ cations" represents the net excess of cations over anions which was accumulated in the sap in the five-hour period. The column " Δ organic acids" represents the increase in organic acids as determined by the method of Isaacs and Broyer (1942). Under the conditions of the experiment, " Δ organic acids" corresponds approximately to the increase in organic anions other than HCO_3^- . As may be seen from the table, the excess accumulation of cations over anions is roughly balanced by organic anions (other than HCO_3^-) which are synthesized within the plant. Moreover, it is apparent that these synthesized organic acids are the ultimate source of the hydrogen which replaces the adsorbed potassium on the clay and not carbonic acid. We are not now attempting consideration of the case of equivalent absorption of cations and anions (*e.g.* K and Br ions) by the plant.

The above findings would seem to indicate that carbonic acid is not involved in the end results of the accumulation reaction. The experiments, however, do not rule out the possibility that carbonic acid may be involved in an intermediate step in the process. For example, one might postulate that the absorption of potassium from clay suspensions takes place by means of the following two steps:

On the assumption of this mechanism the H_2CO_3 can be regarded as a carrier of K^+ between the clay and root surfaces.

The available experimental evidence necessitates ascribing to carbonic acid an intermediate rôle in the cation absorption process in clay systems. Whether or not its direct function as a carrier is important is the subject of current researches in this laboratory. However, it should be pointed out that such a mechanism as outlined in (2) will by no means account for

³ This value includes organic acid anions and undissociated organic acids. For this reason, a balance between total cation and anion is not readily made. Further, the cation total should include H^+ and organic bases.

^b Not determined.

certain experimental observations; for it is inconceivable that the concentration of bicarbonates in the intermicellar liquid will at any time be higher than in the suspension when saturated with CO_2 at one atmosphere pressure. As already noted, recent investigations by Overstreet and Jenny (1939) concerning the absorption of sodium from sodium bentonites revealed that the rate of Na^+ absorption from the intermicellar liquid of the CO_2 -saturated suspension was at all concentrations much less than the rate of absorption from the original suspension.

The contact hypothesis.—The inorganic cations in soil and prepared clay suspensions are for the most part adsorbed on the surfaces of the colloidal particles. The contact hypothesis is based on the fact that these ions, although held in the adsorbed state, are capable of entering into certain chemical processes. While abundant experimental support for this fact is at hand, the theory of the processes cannot be treated rigidly by means of thermodynamics, since the quantities involved (for example, the electric potential in the neighborhood of a charged colloidal surface) are incapable of thermodynamic definition. An extra-thermodynamic interpretation of the problem, along the lines of that used by Debye and Hückel for the case of strong electrolytes, will be published elsewhere. The qualitative aspects of the contact theory may be presented with the adoption of the idea of a diffuse ion swarm about each particle. On this basis the adsorbed ions move rapidly about in a region near the external surface of the particle, much as O_2 molecules move about in the earth's atmosphere. The mean concentration of the ions as a function of the distance from the particle wall depends, among other things, on the particle charge and on the mean concentrations of anions and cations in the system. In the K-clay suspensions discussed above, the concentration of K ions presumably reaches a constant low value at a distance of a few hundred Ångströms from the particles.

With the aforementioned picture of the adsorbed ions, Jenny and Overstreet (1938) have envisaged two distinct types of phenomena occurring in colloidal systems.

The first phenomenon has to do with the ion swarm about a single surface. If by some process a particular ion species is introduced at a given point in the ion swarm, it would be expected to distribute itself in a definite manner throughout the entire ion swarm. This reaction has been termed "the surface migration of adsorbed ions."

The second phenomenon concerns two distinct surfaces having ion swarms which approach very close to one another. In this case the ion swarms would be expected to intermingle. On separation of the surfaces, it would be found that ions from the swarm of the one surface had been transferred to that of the other surface and *vice versa*. This process has been designated as "contact exchange of ions." In this process a transfer of ions from one surface to another takes place which is essentially independent of the intermicellar liquid. On the basis of this mech-

anism Jenny and Overstreet have sought to interpret the absorption of cations by plant roots from soil colloids. By postulating that the root itself possesses an ion swarm about its surface (which cannot now be defined with precision) they were thus able to explain the initial step in cation absorption from soils without resorting to assumed intermediate reactions involving carbonic acid.

In conclusion, it should be pointed out that the two hypotheses outlined in this paper are not necessarily in opposition. The mechanisms are not mutually exclusive. The carbonic acid hypothesis represents an approach to the problem of availability in soils by way of studies with artificially-prepared nutrient solutions. In several respects this approach is justified; for example, certain nutrient anions such as NO_3^- and SO_4^{2-} are contained exclusively in the intermicellar liquid or soil solution. The contact mechanism, on the other hand, is an interpretation of the problem from the viewpoint of surface chemistry. This approach was prompted by a realization of the general inadequacy of solution culture and soil solution studies for the estimation of nutrient availability in the soil system as a whole. While it seems established that the carbonic acid theory alone will not explain certain observable phenomena, the question whether or not the contact theory can withstand the same test must await further experimentation.

SUMMARY

With the use of flowing K Cl culture solutions containing radioactive K, a determination of the influence of concentration on the rate of potassium absorption by barley roots was made for very short time intervals. An approximate value for the maximum absorption rate per unit area of root surface is calculated for the more active regions of the tissue.

A determination was made of the magnitude of the carbonic acid liberation by absorbing roots in K-bentonite suspensions as a function of time.

The relationship between organic acid synthesis by roots and ion absorption from K-bentonite suspensions and potassium salt solutions was investigated. It is concluded that carbonic acid, if involved at all, must play an intermediate rôle in cation absorption from clay suspensions.

Proposed mechanisms for cation absorption by roots in soil and clay suspensions are discussed.

THE SIGNIFICANCE OF X-RAYS IN STUDYING THE ORIENTATION OF CELLULOSE IN THE SECONDARY WALL OF TRACHEIDS¹

I. W. Bailey and Earl E. Berkley

MUCH EVIDENCE has accumulated from varied lines of research which indicates that the orientation of cellulose fluctuates more or less conspicuously in passing from the first-formed to the last-formed part of the walls of plant cells. In the case of normal tracheids of gymnosperms and dicotyledons, the secondary wall is commonly a three-layered structure; the first-formed and the last-formed lamellae of this wall have cellulose that is transversely oriented or arranged in helices of relatively low pitch, whereas the intervening lamellae have cellulose that is oriented longitudinally or in helices of comparatively steep pitch.

Although admitting changes of orientation in the cell wall of *Valonia* and of various tissue cells, Preston (1934, 1939) maintains that there is but a single spiral arrangement of cellulose throughout the secondary wall of coniferous tracheids. The chief evidence presented in support of such a divergent view consists of a small photograph obtained by X-raying a tracheid isolated from wood by maceration. Neither this photograph nor its enlargement exhibit a clearly defined diffraction pattern.

In the case of cotton, ramie and other plant fibers, significant data are obtained by X-ray analyses of aggregates or bundles of cells. Thus, in view of the fact that the structurally simpler types of wood are composed largely of longitudinally oriented tracheids, it is reasonable to anticipate that pertinent data may be obtained by X-raying small pieces of secondary xylem. That such is indeed the case has been demonstrated by Stillwell (1933), Sisson (1935, 1938) and others. It should be emphasized in this connection, however, that in selecting and preparing material for X-ray analysis and in interpreting diffraction patterns, it is essential to be fully cognizant of the numerous morphological, histological, chemical and other variables in the material that is

being studied. For example, certain serious misconceptions concerning the composition of the primary wall of the cotton hair might have been avoided by an accurate visualization of the significance of such variables (Berkley, 1939).

It is advisable, therefore, before discussing X-ray analyses of wood to evaluate the evidence that has accumulated from varied lines of research regarding the visible structure of the secondary wall of tracheary cells.

VISIBLE STRIATIONS AND FIBRILLAR ORIENTATIONS IN THE UNSWOLLEN WALLS OF TRACHEIDS.—Preston (1934) states that "in general no indication is given, visible under an ordinary microscope, of the direction of the cellulose fibrils in the walls" of tracheids. This is an untenable premise. Striations, such as are characteristic of *Valonia* and of various tissue cells, are visible in the secondary walls of many tracheids, provided that the cells are not mounted in media of unfavorable indices of refraction. Freshly cut, moist, longitudinal sections of the wood of living trees fortunately are suitable for microscopic examination and may be studied without staining, chemical pretreatments, or the use of mounting media. Detailed investigations of such sections demonstrate that the first-formed and the last-formed parts of the secondary wall have striations that are transversely oriented to the long axis of the cells or are arranged in helices² of relatively low pitch (45° – 90°), whereas the intervening part of the wall exhibits striae that are longitudinally oriented or arranged in helices of comparatively steep pitch (0° – 45°). As in *Valonia* and other plant cells, these striations are due fundamentally to the fibrillar structure of the cellulosic

² The term, helical, is used in a descriptive sense without rigid geometrical implications. The tracheids of conifers rarely are perfectly cylindrical, but tend to have more or less conspicuously flattened sides. The pitch of the helix changes not infrequently in passing from one surface of the cell to another.

¹ Received for publication November 5, 1941.

matrix and may be differentiated without difficulty from slip planes, cracks, pressure ridges, parallel scratches and other abnormalities mechanically induced by the edge of a knife in sectioning.

It is evident, accordingly, that sections from freshly cut wood of living trees may be utilized as controls or bases of comparison in studying the effects of various chemical and other treatments upon the orientation of the cellulosic fibrils in tracheary cells. When such sections are immersed for a few minutes in chlorine water, stained in iodine-potassium iodide and mounted under a cover glass in a

crystals are equally conspicuous in transverse, longitudinal and diagonal sections of wood, they provide a useful and reliable means of studying fluctuations in the orientation of cellulose in the successively formed parts of the secondary wall. Evidence that may be obtained by this technique cannot be brushed aside upon the mere assumption that the deviations in orientation are induced by swelling. In the first place, the crystals form in dilutions of sulphuric acid—50 per cent or less—which produce no detectable swelling in heavily lignified cell walls. In the second place, the visible striae in untreated sections have

Fig. 1-5. Orientation of crystals in the outer and central layers of the secondary walls of tracheids.—Fig. 1. Transverse orientation in outer layer. $\times 840$.—Fig. 2. Pitch of 60° in outer layer. $\times 840$.—Fig. 3. Pitch of 40° in central layer. $\times 840$.—Fig. 4. Pitch of 10° in central layer. $\times 750$.—Fig. 5. Longitudinal orientation in central layer. $\times 1,560$.

small drop of diluted sulphuric acid, crystals of iodine may be induced to form in the elongated porosities of the cellulosic matrix (Bailey and Vestal, 1937a). The long axis of these slender crystals³ is oriented parallel to the long axis of the porosities and, therefore, *pari passu* to the long axis of the fibrils. In other words, where the visible striae or fibrils are longitudinally oriented, the crystals are arranged parallel to the long axis of the cell (fig. 5); where the striae are transversely oriented, the crystals are arranged at right angles to the long axis of the cell (fig. 1), and where the striations have a helical orientation, the crystals are arranged in a helix of identical pitch (fig. 2-4). Since the dark-colored

³ The size and the number of the crystals may be altered by varying the details of the technique. Numerous minute crystals are desirable for accurate visual study of the fibrillar orientations in adjacent lamellae, but larger crystal complexes are advantageous for photographic illustration (fig. 1-5).

similar orientations. In the third place, even the swelling produced by stronger acid—50 per cent to 60 per cent—does not induce changes of from 45° to 90° in the fibrillar orientations of the inner (last-formed) and outer (first-formed) layers of such heavily lignified secondary walls. Nor can the swelling produce abrupt transitions in adjacent lamellae from right-handed to left-handed helices or *vice versa*.

EFFECTS OF DRYING UPON FIBRILLAR ORIENTATIONS.—Many investigations in the past have been based upon the study of cells or tissues that at some stage have been dried below the fiber saturation point. For example, the customary procedure in preparing fibers for X-ray analyses involves a thorough drying. Both primary and secondary walls contract in drying along planes at right angles to the long axis of the fibrils. The contraction of the walls, in turn, produces more or less extensive changes in the

form and the dimensions of the cells; the type and the magnitude of which depend upon a wide variety of factors. Obviously the orientation of the fibrils may be modified during the process of drying. Therefore, microscopic observations and X-ray analyses of desiccated material provide reliable evidence regarding the orientation of fibrils, crystallites and chain molecules in *dry* specimens, but do not *necessarily* provide an accurate picture of the orientations in cells that have never been dried below the fiber saturation point. It is essential in each particular case to obtain some clue regarding the changes that may have occurred during drying.

Longitudinal sections of the freshly cut wood of living trees may be mounted under a cover glass and kept under continuous microscopic observation throughout the entire process of desiccation. As the sections dry, the visible striations of the secondary wall of the tracheids become increasingly conspicuous. In the case of the normal wood of coniferous species and of the vesselless dicotyledon, *Trochodendron*, there are minor readjustments during drying, but there are no extensive changes in the orientation of the fibrils except possibly in the corners of rectangular or hexagonal cells. Therefore, X-ray analyses of wood which has not become excessively warped or deformed during drying should yield fairly close approximations to the orientations of cellulose in unseasoned wood.

EFFECTS OF DELIGNIFICATION AND MACERATION UPON FIBRILLAR ORIENTATIONS.—Numerous investigations in the past have been based upon the microscopic study of pulp or of cells that have been isolated by maceration. Furthermore, in obtaining sharply defined X-ray diffraction patterns of the cellulose in wood, it is necessary to remove most of the non-cellulosic constituents, particularly the lignin. Therefore, it is essential to determine what effects delignifying and macerating reagents have upon cellulose. In the case of the woods that were selected for investigation, it is possible to delignify and macerate longitudinal sections and to study the microscopically visible effects of specific reagents upon the fibrillar orientations of the cellulose. As in drying woods, minor readjustments of form and structure occur during delignification⁴ and maceration, but there are no pronounced changes in the fibrillar orientations. Walls having layers with transverse, longitudinal, right-handed or left-handed helical orientations, retain these orientations throughout the processes of delignification and of maceration. This is of considerable significance since it justifies the study of fibrillar orientations in single cells or in pieces of cell wall. Thus, the complications of accurately focusing through adjacent cells or cell walls may be avoided. It indicates, in addition, that data obtained by the micro-dissection of isolated cells (Seifriz and Hock, 1936) cannot be ignored or rejected upon the

⁴ That the removal of lignin and cellulose from wood causes no fundamental change in the X-ray diffraction pattern of cellulose is indicated by the work of Preston and Allsopp (1939).

assumption that the fibrillar orientations were extensively modified during maceration.

CORRELATIONS BETWEEN FIBRILLAR ORIENTATIONS AND ANISOTROPY.—Physical evidence has accumulated in recent years which indicates that the chain molecules and crystallites of cellulose are oriented within fibrils with their long axes parallel to the long axis of the fibrils. Isolated macro-fibrils exhibit positive optical anisotropy and sharply defined extinction angles. Thus, the optical anisotropy of the various layers of the cell wall should correlate closely with the visible fibrillar orientations within them. Where the striae or fibrils of the central layer of the secondary wall of tracheids are longitudinally oriented, this layer should exhibit no birefringence under the polarizing microscope in transverse sections of the wood; it should show intense birefringence in longitudinal sections, and more or less reduced birefringence in sections cut at varying diagonals to the long axis of the cell. Conversely, where the fibrils of the inner and outer layers are oriented at right angles to the long axis of the cell, these layers should exhibit intense birefringence in transverse sections of wood, more or less reduced birefringence in diagonal sections, and no birefringence in those parts of longitudinal sections where plane surfaces of the walls can be viewed edge on. Where the layers have helical orientations, they should be more or less birefringent in both transverse and longitudinal sections, depending upon the pitch of the helix, and should exhibit no birefringence on one side of the cell in certain specific planes of diagonal section. Where a layer has a helical orientation of approximately 45°, this layer should be dark on one side of the cell and intensely birefringent upon the opposite side in sections cut at an angle of 45° to the long axis of the cell.

All of these theoretical predictions have been fully verified in woods of conifers and dicotyledons (Bailey, 1940) but there are certain of them—those involving absence of birefringence—which require unusually favorable material and great care in sectioning for convincing proof. To demonstrate the absence of birefringence from longitudinally striated layers⁵ in transverse sections of wood, it is essential in the first place to find specimens in which the tracheids are straight and are uniformly oriented with their long axis parallel to the vertical axis of the tree. Such specimens are by no means of common occurrence. In the second place, the plane of sectioning must be oriented with precision at right angles to the long axis of the tracheids and the sections must be cut with a very thin, perfectly smooth and properly oriented knife edge which does not produce serious distortions of the fibrils in sectioning. In the case of layers having fibrils arranged in planes at right angles⁵ to the long axis of the tracheids, it is essential to obtain accurately oriented longitudinal sections from wood composed of large tracheids with flattened parallel

⁵ Wall layers having a perfectly uniform orientation of fibrils throughout all of their constituent lamellae are of exceptional, rather than of typical, occurrence in tracheids.

sides. In such sections only is it possible to eliminate the complicating effects of wall curvatures. It should be noted in this connection that no critical evidence can be obtained under the polarizing microscope from sections of the quality illustrated by Preston (1939).

Cellulose swells considerably in planes at right angles to the long axis of the fibrils, but only slightly in a plane parallel to this axis. Therefore, if the inner and the outer layers of the secondary wall of the tracheids have fibrillar orientations which deviate markedly from that of the central layer, these layers should exhibit characteristic and predictable differences in swelling anisotropy. Where the fibrils of the outer layer are transversely oriented or are arranged in helices of low pitch—i.e., nearly at right angles to those of the central layer—the outer layer should not increase in circumference during swelling, but should act as a constricting cylinder about the laterally expanding central layer. Numerous evidences of this constricting behavior of the outer layer may be observed in the swelling of isolated tracheids and of transverse sections of wood (Bailey, 1940).

CORRELATIONS BETWEEN FIBRILLAR ORIENTATIONS AND PLANES OF ENZYMATIC HYDROLYSIS.—There are certain ubiquitous fungi whose hyphae penetrate and move forward within the secondary walls of tracheary cells. Enzymatic hydrolysis progresses along two sets of predetermined planes, one of which is oriented parallel to the long axis of the fibrils of cellulose (Bailey and Vestal, 1937b). The hyphae and the elongated cavities which they produce are oriented with their long axes parallel to the long axis of the fibrils. Where the hyphae penetrate the inner and the outer layers of the secondary walls of tracheids, they are oriented transversely or in helices of low pitch, whereas in the central layer of such walls, they are oriented longitudinally or in helices of comparatively steep pitch with respect to the long axis of the tracheids.

UNRELIABLE INDEXES OF FIBRILLAR ORIENTATIONS.—Various investigators have attempted to determine fibrillar or micellar orientations by measuring the extinction angles of cell walls in surface view. Such measurements lead to serious misconceptions, however, when derived from walls that are composed of two or more layers of fluctuating thicknesses and different fibrillar orientations. The problem is further complicated in the case of many tracheids where the orientation of the fibrils fluctuates considerably in the successively formed lamellae of the individual layers of the secondary wall or even within different parts of the same lamellae.

In the case of thick secondary walls of the three-layered type, the long axis of the slitlike pit orifices is frequently oriented approximately parallel to the fibrillar orientation of the central layer, but affords

no evidence regarding the fibrillar orientations of the inner and outer layers of the cell wall. In thin-walled tracheids, the pit orifices commonly afford no reliable clues concerning the fibrillar orientations of any of the wall layers. Similarly, planes of mechanical cleavage may afford useful evidence in the case of radio-longitudinally or radio-helically striated layers, but are difficult to interpret accurately in the case of other types of wall layers.

CONCLUSIONS REGARDING VISIBLE ORIENTATIONS.—It is evident from the preceding discussion that the fibrillar orientations of cellulose fluctuate more or less markedly in passing from the first-formed to the last-formed lamellae of the secondary walls of tracheids, and that the most reliable means at present of demonstrating such deviations in orientation are microscopically visible striations and crystals that may be induced to form in the elongated porosities of the cellulosic matrix. The close correlation between fibrillar orientation, optical anisotropy, swelling anisotropy, and predetermined planes of hydrolysis supports the view that the chain molecules and crystallites of cellulose are oriented within fibrils with their long axes parallel to the long axis of the fibrils. If the chain molecules are so oriented in the fibrils of tracheids, it should be possible under favorable circumstances to correlate salient features of X-ray diffraction patterns with visible fibrillar orientations.

SELECTION AND PREPARATION OF WOOD FOR X-RAYING.—In obtaining X-ray diffraction patterns from wood, it is essential to reduce the number of morphological, histological, chemical and other variables to a minimum, and in any case to obtain reliable evidence regarding the significance of such variables in the material that is being analyzed. In dealing with tracheids it is advisable to use wood which is devoid of vessels and contains a low percentage of parenchyma. Straight-grained secondary xylem from the outermost part of the stems of large conifers and of the vesselless dicotyledon, *Trochodendron*, provide favorable material for X-ray analyses. In such specimens, the tracheids are of large size, thus reducing the ratio of tapered ends within the limits of a unit area. Furthermore, the tracheids tend to be arranged in more uniform serialations, and the curvature of the growth rings is greatly reduced. The problems of X-ray analysis may be further simplified by separating the early wood from the late wood. To facilitate this procedure, it is desirable to select wood having very sharply and abruptly defined layers of dense late wood. However, before dissecting small cubes of wood into their constituent layers of early wood and late wood, it is essential to cut transverse, radial and tangential sections for microscopic study and as permanent records of the specific combinations of

morphological and histological variables in each specimen that is analyzed.

In the X-ray analyses reported here, small pieces of early wood and late wood were used, which had tangential surfaces of 4×6 millimeters and radial thicknesses of from 1 to 2.5 millimeters. These specimens were first treated successively with hot alcohol, benzene, ether, chloroform and acetone for the extraction of fats, waxes, terpenes, resins, etc. The specimens were subsequently delignified by alternating treatments with chlorine water and dilute alcoholic ammonium hydroxide.⁶ The use of the latter reagent at room temperature, instead of hot sodium sulphite, enables one to remove the bulk of the lignin from wood without macerating the tissue. Much care must be exercised in drying the delignified specimens to prevent undue warping and splitting. Undelignified specimens should be retained as controls, since the more conspicuous features of the diffraction patterns of cellulose frequently may be detected in spite of the amorphous fogging produced by lignin and other amorphous constituents.

In obtaining X-ray diffraction data from wood, it is desirable to compare the diffraction patterns obtained by passing the X-ray beam (a) parallel to the long axis of the wood rays, *viz.*, *radially*, (b) at right angles to the long axis of both the tracheids and the wood rays, *viz.*, *tangentially*, (c) at right angles to the long axis of the tracheids and at 45° to the long axis of the wood rays, *viz.*, *diagonally*, and (d) parallel to the long axis of the tracheids, *viz.*, *longitudinally*. Furthermore, in making accurate analyses, it is advisable to obtain micro-photometric readings from the original negatives, since such data frequently reveal intensity maxima which may be overlooked in a visual examination.

A detailed discussion of the data will be presented in a subsequent paper dealing with the more purely physical aspects of the problem. Thus, the corroborative microphotometric data, with one exception, are omitted from this paper and illustrations of diffraction patterns are reduced to an essential minimum.

DIFFRACTION PATTERNS OF LATE WOOD.—The conventional procedure in dealing with cotton, ramie and other fibers is to orient the cells with their long axis at right angles to the beam of X-rays. Figure 7 illustrates a diffraction pattern obtained by passing a beam of X-rays through the late wood of *Pinus longifolia* Roxb. at right angles to the long axis of the tracheids and parallel to the long axis of the wood rays. This diffraction pattern closely resembles that of ramie, which is considered to be indicative of a very uniform orientation of chain molecules approxi-

⁶ 150 cc. ammonium hydroxide, sp. gr. 0.90, to 850 cc. 95 per cent ethyl alcohol.

mately parallel or in a spiral of about 3° to the long axis of the cell. This particular sample of wood was selected for X-raying because the broad central layer of the secondary walls of the tracheids exhibits unusual regularity in the orientation of visible striations and of crystals (fig. 5) parallel to the long axis of the tracheids. Thus, there is a perfect correlation between the X-ray diffraction pattern and the fibrillar orientation of cellulose in the central layer of the secondary wall.

It is significant in this connection, however, that the fibrils of the tenuous inner and outer layers of the secondary wall are oriented either transversely (fig. 1) or in helices of relatively low pitch (fig. 2). Therefore, these layers are intensely birefringent in transverse sections of the wood (fig. 6), whereas the central layer exhibits no birefringence even in relatively thick sections. The fibrillar orientations of the inner and outer layers of the secondary wall obviously produce no detectable effects in the X-ray diffraction pattern. This is due to two sets of factors. In the first place, the fibrillar orientation of the inner and outer layers fluctuates considerably not only in different cells, but also in different parts of the same cell. In other words, the angle of inclination is not constant as in the central layer, but fluctuates between 60° and 90° . Therefore, the diffractions produced by the inner and outer layers are diffused over broad arcs rather than concentrated in localized interference spots. In the second place, recent work with cotton (Berkley, 1939) has demonstrated that the orientation of the cellulose in the tenuous primary wall of the cotton hair cannot be detected in X-ray patterns after the secondary wall attains any considerable thickness. The inner and outer layers of the secondary walls in the late wood of *Pinus longifolia* are too tenuous in comparison with the breadth of the central layer for both sets of diffractions to be detected simultaneously. For similar reasons, the walls of the wood rays produce no visible images.

Figure 9 illustrates a diffraction pattern obtained by passing a beam of X-rays through the late wood of *Sequoia sempervirens* Endl. at right angles to the long axis of the tracheids and parallel to that of the wood rays. This particular sample of wood was selected for X-ray analysis because it exhibits the following combination of visible structural characters. The inner and the outer layers of the secondary wall are unusually thick⁷ and the fibrils of these layers exhibit considerable uniformity of orientation at right

⁷ The apparent thickness of the layers in polarized light is deceptive. Accurate measurements of the average breadth of the layers must be made under high magnification with non-polarized light.

Fig. 12-17. X-ray diffraction patterns.—Fig. 12. *Sequoia sempervirens*, late wood, X-ray beam perpendicular to the long axis of both the tracheids and the wood rays, *viz.*, tangentially oriented.—Fig. 13. The same, X-ray beam perpendicular to the long axis of the tracheids and at 45° to the long axis of the wood rays, *viz.*, diagonally oriented.—Fig. 14. *Picea rubra*, "compression wood," X-ray beam perpendicular to the long axis of the tracheids and parallel to the long axis of the wood rays, *viz.*, radially oriented.—Fig. 15. *Pinus ponderosa*, "compression wood," X-ray beam radially oriented.—Fig. 16. *Trochodendron aralioides*, early wood, X-ray beam radially oriented.—Fig. 17. *Sequoia sempervirens*, early wood, X-ray beam radially oriented.

angles to the long axis of the tracheids. The fibrillar orientation of the central layer is helical, the pitch fluctuating within relatively narrow limits, *viz.*, between 30° and 40° . Therefore, all three layers of the secondary wall exhibit anisotropy in transverse sections of the wood (fig. 8), but the inner and outer layers are more intensely birefringent than the central layer.

In the X-ray pattern (fig. 9) there are four pairs of conspicuous diffraction maxima in both the 002 and 101 diffraction rings. The long axes of the tracheids were arranged vertical to the page; therefore, reading clockwise from the top of the pattern, the pairs of maxima may be observed at approximately 0° and 180° , 52.5° and 232.5° , 90° and 270° , 127.5° and 307.5° , each pair presumably representing a set of fibrils or crystallites in the cell wall. The two pairs of interference spots at 52.5° and 232.5° and at 127.5° and 307.5° are indicative of a helical orientation of chain molecules with a pitch of approximately 37.5° . The two pairs result from the same spiral but from opposite tangential walls of the tracheids. The somewhat less conspicuous maxima of both the 002 and 101 diffraction rings at 0° and 180° are indicative of a transverse orientation of chain molecules, *viz.*, approximately at right angles to the long axis of the tracheids. The diffraction maxima at 90° and 270° suggest a third orientation of chain molecules parallel to the long axis of the cells. The helical and transverse orientations of chain molecules obviously correlate closely with the visible fibrillar orientations of the central layer and of the inner and outer layers of the secondary walls of the tracheids, since they occur in X-ray diffraction patterns obtained by passing the X-ray beam perpendicular to the long axis of the tracheids but in the radial, the tangential, and diagonal directions to them (fig. 9, 12, and 13). On the contrary, there are no visible longitudinal orientations in the tracheids which may be correlated with the diffraction maxima at 90° and 270° . Furthermore, the form, arrangement, and wall structure of the ray cells is such that these diffraction maxima cannot be attributed to them.

For the solution of such a paradox attention must be devoted to a study of the effects of variations in the shapes of cells and the thickness of the different wall layers upon X-ray diffraction patterns. Most of the tracheids in the wood of *Sequoia sempervirens* are rectangular (fig. 8). The broad, flattened, tangential walls are oriented at right angles to the beam of X-rays, whereas the radial walls are oriented parallel to the beam when it is passed perpendicular to the long axis of the tracheids and parallel to the long axis of the wood rays. Similarly the tangential walls would be parallel and the radial walls perpendicular to the beam when it is passed in the tangential direction. Curved surfaces, the parts between the radial and tangential walls, are reduced to a minimum in this sample. Three of the four pairs of interference spots in figure 9 obviously are due to the diffraction of X-rays in passing through the tangential walls of the tracheids. The diffraction maxima at 90° and

270° on the other hand are apparently due to X-rays which pass through the radial walls of the tracheids and are diffracted by the transverse cellulose in the outer and inner layers of the secondary wall. These spots were more pronounced, as would be expected from the more uniform diffracting surface presented by the tangential walls (fig. 8) when the X-ray beam was passed perpendicular to the long axes of both the tracheids and the wood rays, *i.e.*, tangentially (fig. 12). Diffractions produced by the curved parts of the walls and by diagonally oriented radial walls tend to produce relatively broad arcs and thus to bridge the gaps lightly between the various sets of interference spots. That the diffraction phenomena in figure 9 may be accounted for without resorting to a hypothetical system of longitudinally oriented chain molecules can be demonstrated by the absence of the spots at 90° and 270° in figure 13, which was obtained by passing the beam of X-rays through the specimen perpendicular to the long axis but diagonal to the radial and tangential surfaces of the tracheids. If the interference spots had resulted from longitudinally arranged cellulose, they should not have disappeared in this pattern. Their disappearance in the diagonal pattern indicates that they were caused by a diffraction of the X-rays by the end-on position of the transverse cellulose in the outer and inner layers of the secondary wall.

DIFFRACTION PATTERNS OF "COMPRESSION WOOD."

—Figure 11 illustrates a diffraction pattern obtained by passing a beam of X-rays through the "compression wood" of *Taxodium distichum* (L.) Rich. at right angles to the long axis of the tracheids and parallel to that of the wood rays. As in figure 9, there are diffraction maxima indicative of helical and transverse orientations of chain molecules, but there are no detectable interference spots to indicate parallel arrangement. The tracheids of this particular specimen of "compression wood" are characterized by their large size, relatively thin ($3.5\ \mu$) secondary walls and somewhat compressed cylindrical form. The fibrillar orientation of the outer layer is dominantly transverse. As in other tracheids of the "Rotholz" type (Hartig, 1896), the inner layer is composed of radio-helical bands, having a pitch of 44° – 48° to the long axis of the tracheids. In this layer, the long axis of the fibrils is oriented parallel to that of the helical bands. Thus, both the inner and the outer layers are conspicuously birefringent in transverse sections of the wood (fig. 10). The isotropy or feeble birefringence of the intervening layer is due, not to a longitudinal orientation of fibrils, but to the fact that this layer is composed largely of non-cellulosic constituents.

The transverse cellulose of the outer layer of the secondary wall will account for the pair of interference spots at 0° and 180° of figure 11. The two pairs of interference spots at approximately 50° and 225° and at 132.5° and 310° can be ascribed to the radio-helical bands of the thick inner layer of the secondary wall. There are no maxima at 90° and 270° such as occur in figure 9. That the absence of

such maxima is correlated with the more cylindrical shape of the tracheids is indicated by the fact that other samples of "Rotholz" (figure 14) having cylindrical tracheids exhibit similar diffraction patterns regardless of variations in the thickness of the secondary wall and of its constituent layers.

Figure 15 illustrates a Debye-Scherrer type of diagram obtained from the "Rotholz" of a young stem of *Pinus ponderosa* Lawson. Such diffraction diagrams are commonly interpreted as resulting from random orientation of cellulose crystallites in the cell wall. It is significant in this connection, however, that the fibrillar orientation as indicated by visible striations, iodine crystals and optical and swelling anisotropy is dominantly transverse in the outer layer of the secondary wall of the tracheids and is prevalingly helical in the inner layer. Furthermore, the tracheids are very short and exhibit—both in radial and tangential views—a high ratio of pronounced curvatures and other deformations, particularly in their tapered upper and lower thirds. *A priori* one would expect the straight parts of the tracheids—i.e., those oriented parallel to the long axis of the stem—to produce diffraction maxima as in figures 11 and 14, whereas the curved and deformed parts would tend to produce a ring-type of diffraction pattern, since the fibrils are oriented at varied angles to the beam of X-rays. The microphotometric readings recorded in figure 18 demonstrate that maxima do occur at 0° and 180° , 45° and 225° , and 140° and 320° which are barely detectable visually in figure 15.

DIFFRACTION PATTERNS OF EARLY WOOD.—The fibrillar orientations in the thin-walled tracheids of early wood fluctuate considerably, not only in different cells, but also in different parts of the same cell, in different lamellae of the same wall layer, and in different parts of the same lamellae. The widest range of variability occurs in the radial walls of the tracheids and is correlated with the occurrence of bordered pits and numerous contacts with ray cells. In general, the fibrillar orientations tend to be steeper in the central layer than in the inner and outer layers and in tangential walls than in radial ones (Bailey and Vestal, 1937a). The thickness of the secondary wall and *pari passu* of the central layer varies considerably in different samples of early wood and between the first-formed and last-formed tracheids of the early wood. Furthermore, it is significant that not infrequently there is less regularity in the form of the tracheids in early wood than in late wood. Many of the large, thin-walled tracheids of the early wood are of hexagonal form. Therefore, there commonly is less uniformity in the orientation of radial walls parallel to the long axis of the rays in early wood than in normal late wood.

In view of such facts as these, one should expect early wood to produce broad arcs or rings of diffraction when X-rayed at right angles to the long axis of the tracheids. Figures 16 and 17 illustrate such diffraction patterns of the early wood of *Trochodendron aralioides* Zieb. & Zucc. and of *Sequoia semper-*

virens Endl. Owing to the tenuous character of the central layer in the tracheids of the early wood of *Trochodendron*, the diffractions produced by the steeper fibrillar orientations (0° — 45°) of this layer tend to blend into those produced by the lower fibrillar orientation (45° — 90°) of the inner and outer layers. On the contrary, in the case of the early wood of *Sequoia* where the central layer is thicker and has a higher ratio of fibrillar orientations between 20° and 45° , the broad arcs of diffractions produced by this layer may be differentiated from those due to the

Fig. 18. Photometric readings from same film as figure 15.

fibrillar orientations (45° — 90°) of the inner and outer layers.

DISCUSSION.—There is a close correlation between the position of the long axis of the visible fibrils in the secondary walls of tracheids and that of the cellulose molecules in the crystallites as shown by the X-ray diffraction patterns that are produced from such walls. In other words, the evidence presented on the preceding pages supports the widely held view that to a large extent the long chain molecules and, therefore, the crystallites of cellulose are oriented within fibrils with their long axis parallel to the long axis of the fibrils. The X-ray data afford no support for Preston's assumption of a single spiral orientation of cellulose throughout the secondary wall of coniferous tracheids. On the contrary, they demonstrate that the orientation of the chain molecules fluctuates markedly in different layers of the secondary walls of coniferous and dicotyledonous tracheids.

With the exception of figure 7, the X-ray diffraction patterns taken perpendicular to the long axis of the tracheids are clearly indicative of more than one orientation of chain molecules and correlate closely with evidence obtained by the study of visible fibrillar orientations, of optical anisotropy, of swelling anisotropy and of predetermined planes of hydrolysis. In the case of the late wood of *Pinus longifolia*, the uniformly longitudinal orientation of fibrils in the broad central layer of the secondary wall correlates perfectly with the isotropy of this layer in transverse sections of the late wood (fig. 6) and with the X-ray diffraction pattern (fig. 7) produced by this layer. The inner and outer layers having fibrillar orientations of from 60° to 90° are intensely birefringent in transverse sections (fig. 6), but are so tenuous in comparison with the thickness of the central layer that they produce no conspicuous diffraction arcs in the X-ray photograph (fig. 7). If it be assumed from the X-ray diffraction pattern that there is a single longitudinal orientation of cellulose throughout the secondary wall, the inner and outer

layers in figure 6 should not exhibit birefringence. If one assumes that there is a single spiral orientation of cellulose throughout the secondary wall and that the appearance of layering is due to considerable angular dispersion of chain molecules within the central layer,⁸ this layer should exhibit some birefringence in transverse sections, and the X-ray diffraction pattern should not indicate such uniform longitudinal orientation of chain molecules.

It should be emphasized again in conclusion that, in selecting and preparing plant material for X-ray-ing and in interpreting X-ray diffraction patterns it is essential to be fully informed concerning the numerous morphological, histological, chemical and other variables in the material that is being analyzed. Where the layers of cell walls vary considerably in thickness, X-ray diffraction patterns may afford no evidence concerning the orientation of chain molecules in the more tenuous layers. Thus, X-ray diffraction patterns of mature cotton hairs give no clue concerning the orientation of cellulose in the primary wall. A ring-type of diffraction pattern is not indicative necessarily of a truly random orientation of chain molecules, but may be due (a) to deviations in the orientation of cellulose in the successively formed lamellae of cell walls, (b) to deviations of orientation in different cells of a particular specimen, (c) to curvatures and other deformations of the shape and orientation of cells within a specific specimen or (d) to a combination of such variables. Furthermore, certain variations in the type of diffraction pattern may be due to the shape and the arrangement of cells within a particular specimen, rather than to peculiarities of the orientation of cellulose within the walls of the cells.

Therefore, in dealing with the tracheids in wood, it is necessary to obtain reliable clues regarding the following variables:

1. The ratio of parenchymatous cells to tracheary tissue and the types of diffractions which they produce.
2. The shape and arrangement of the tracheids in transverse sections of the wood.
3. The shape and arrangement of the tracheids in radial and tangential longitudinal sections of the wood.
4. The comparative thickness of the wall layers.
5. The fibrillar orientations in the successively formed lamellae of these layers.

⁸This is contradictory, since the angularly dispersed chain molecules are not in alignment with a single spiral orientation. In Preston's (1939) revised diagram the alignment of chain molecules in surface view of the central layer does not correspond with the orientations figured in sectional views of this layer.

6. Fluctuations in the fibrillar orientations in different tracheids of the same specimen and in different surfaces of the same cells.

7. Morphological changes that may occur during chemical pretreatments and drying.

SUMMARY

The most reliable means at present of studying the fibrillar orientations of cellulose in individual layers of tracheids are microscopically visible striations and crystals that may be induced to form in the elongated porosities of the cellulosic matrix of unswollen walls. The over-all average or dominant arrangement of the crystalline cellulose may be best obtained from X-ray diffraction patterns.

Careful drying, delignification and maceration of wood produce minor changes in the orientation of fibrils but no pronounced deviations in orientation, such as from longitudinal to transverse or from right-handed to left-handed helices, etc.

There is a close correlation between fibrillar orientation, optical anisotropy, swelling anisotropy, predetermined planes of hydrolysis and X-ray diffraction patterns. This indicates that the chain molecules and crystallites of cellulose are oriented within fibrils with their long axis parallel to the long axis of the fibrils.

The fibrillar orientations of cellulose in the secondary walls of tracheids fluctuate markedly, not only in wood from different parts of the same tree but also in different layers of the same cell wall and frequently also in different lamellae of the same layer.

The fibrillar orientations of the inner and outer layers fluctuate between transverse and helices of comparative low pitch (45° – 90°), whereas those of the central layer usually deviate between longitudinal and helices of relatively steep pitch (0° – 45°). Uniform orientation of cellulose throughout the successive lamellae of a wall layer is exceptional rather than typical of tracheids.

The use of the polarizing microscope and of X-ray diffraction patterns alone may lead to serious misconceptions regarding the orientation of cellulose in cell walls, unless the numerous morphological, histological, chemical and other variables in plant materials are accurately visualized and accounted for.

SPECIFICITY OF PYRIDOXINE FOR EXCISED TOMATO ROOTS¹

William J. Robbins

ROBBINS AND SCHMIDT (1939a, 1939b) reported that pyridoxine (vitamin B₆) beneficially affected the growth of excised tomato roots in a mineral-sugar solution containing thiamin. Bonner and Devirian (1939) found pyridoxine without effect upon the growth of excised roots of peas, radish and flax but obtained positive results with those of tomato. Bonner (1940) found no effect on excised roots of alfalfa, clover, or cotton but beneficial results with excised roots of *Datura stramonium*, sunflower, carrot and five strains of tomato. Stoutmeyer (1940) reported the rooting of the cuttings of some kinds of plants was improved by applications of pyridoxine, while others showed no response. Robbins (1941) found the excised roots of two inbred strains of tomato and their heterotic hybrid offspring to respond to pyridoxine in the presence of thiamin. White (1940) concluded that pyridoxine was of no benefit to the growth of excised tomato roots. Day (1941) found pyridoxine beneficial to the growth of excised tomato roots in an agar medium containing thiamin.

The present paper is not intended to account for the failure of White to obtain the beneficial effects of pyridoxine on excised tomato roots observed by Robbins and Schmidt, by Bonner and Devirian, by Bonner, by Robbins, and by Day, but to report on the specificity of the compound. Many of the vitamins and vitamin-like growth substances show a high degree of specificity; a small change in molecular structure reduces their effectiveness or eliminates it entirely. Other work which will not be reviewed here has shown the specificity of thiamin, nicotinic acid, riboflavin and pantothenic acid. The effect of pyridoxine on excised tomato roots also is quite specific.

METHODS AND MATERIALS.—The strain of excised tomato roots employed in these experiments was that originally isolated by Robbins and Schmidt (1938). This strain has been in culture since September, 1935, and has been maintained by transfers at monthly intervals in a mineral-sugar solution containing thiamin since October, 1936, and in a mineral-sugar solution containing the thiazole² inter-

mediate of thiamin since April, 1937. The numerous successive passages in a solution limited to mineral salts, sugar and thiamin on the one hand or to mineral salts, sugar and thiazole on the other insure that the roots used as inoculum in the experiments reported here contained no growth substances not synthesized by the roots other than thiamin or its derivatives.

The excised tomato roots were grown individually in 125 ml. Erlenmeyer flasks each containing 50 ml. of a modified Pfeffer's solution³ and either 1 per cent or 2 per cent cane sugar as indicated. The roots were incubated at 25°C. in diffuse light.

For inoculation, a root which was three or four weeks old was fragmented by a razor blade into pieces about a centimeter long. One fragment was transferred to each flask in which the effect of pyridoxine or an analogue was to be observed. Each fragment contained one or more growing points.

All glassware, as is customary in my laboratory, was thoroughly cleaned with chromic acid cleaning mixture or with a nitric-sulfuric acid cleaning mixture and thoroughly rinsed with tap water and distilled water. All chemicals were of chemically pure grade. The pyridoxine and thiamin were Merck's synthetic preparations.

Through the courtesy of Merck and Co. the following analogues of pyridoxine were obtained. For convenient reference the identification number⁴ furnished by Merck and Co., as well as the name of each compound is given:

- 39RD1421 Hydrochloride of triacetate of vitamin B₆.
- 39RD1422 Hydrochloride of diacetate of vitamin B₆.
- 39RD1442 Hydrochloride of B-methyl ether of vitamin B₆.
- 39RD1443 Hydrochloride of 2, 4, 5 trimethyl-3-hydroxypyridine.
- 39RD1029 2-methyl-3-amino-4-hydroxymethyl-5-amino-methyl pyridine dihydrochloride.
- 39RD1030 2-methyl-3-hydroxy-4-ethoxymethyl-5-hydroxymethyl pyridine hydrochloride.

³ This solution contained per liter 0.333 g. Ca(NO₃)₂, 0.083 g. MgSO₄·7H₂O, 0.083 g. KNO₃, 0.042 g. KCl, 0.083 g. KH₂PO₄ and 0.0025 g. Fe₂(SO₄)₃. In addition the following trace elements were added in ppm.: 0.05 B, 0.05 Mn, 0.005 Zn, 0.002 Cu and 0.005 Mo.

⁴ For brevity the portion of these numbers, 39RD or 41RD, is omitted later in referring to these compounds; for example, compound 39RD1421 is called #1421.

Each of these compounds was added in amounts of 1, 10 and 50 millemicromoles ($m\mu$ moles) per flask in the presence of 10 $m\mu$ moles of thiamin. The growth of the excised tomato roots in solutions supplemented with the pyridoxine analogues was compared with their growth in solutions supplemented with molecularly equivalent amounts of pyridoxine. Five replications of each treatment were usually used, but in some instances ten replications were employed. Observations were made at intervals during the course of each experiment, and at the end of about two months the roots were dried at 100°C. and weighed.

EXPERIMENTAL RESULTS.—The diacetate and triacetate of pyridoxine (#1421 and #1422) were as effective as pyridoxine. Roots which had grown for twenty-eight successive passages in a mineral-sugar solution containing thiazole were used for inoculum. The Pfeffer's solution contained 2 per cent sugar, and the roots were grown from October 12, 1939, to December 14, 1939 (table 1). The pyridoxine analogues in this experiment had been added to the nutrient solutions before sterilization in the autoclave, and it was thought that the heating might have caused decomposition with the formation of free pyridoxine. The experiment was repeated, but the diacetate and triacetate were filtered sterile and added to the nutrient solution after it had been sterilized with heat. In this instance also the acetates

were as effective as pyridoxine. Not only was the amount of growth obtained with the acetates equal to that secured with molecularly equivalent quantities of pyridoxine, but the appearance of the roots was the same. The hooks and curls previously described (Robbins and Schmidt, 1939b) in solutions containing thiamin and pyridoxine were observed also in the solutions containing the acetates.

Compound #1442 differs from pyridoxine in having a methoxy group in place of the hydroxyl group in the third position on the pyridine ring (table 4). It was not effective as a substitute for pyridoxine (table 1). Because of the possible benefit from 1 $m\mu$ mole of compound #1442 (table 1), the experiment was repeated with additions of 1, 2, 10 and 50 $m\mu$ moles of the compound per flask. These proved ineffective.

Compound #1443 differs from pyridoxine in having the hydroxymethyl groups in the fourth and fifth positions replaced by the methyl radical. This substance did not replace pyridoxine for excised tomato roots (table 1).

Similar results were obtained with compounds #510, #511, #1029, #1030, #1031, and #1032 (table 2). In this experiment fragments of roots which had grown for thirty-one passages in Pfeffer's solution supplemented with thiamin were used for inoculum, and the experiment ran from June 23, 1939, to August 24, 1939. Of these #510, #511, #1029 and #1032 had neither a marked beneficial nor detrimental effect up to 50 $m\mu$ moles per flask;⁵ #1031 inhibited growth somewhat where 50 $m\mu$ moles were added per flask, and #1030 was decidedly toxic even when 10 $m\mu$ moles were present (table 2). The last compound is of particular interest because it differs from pyridoxine only in having an ethoxymethyl group in the fourth position on the

⁵ It is doubtful whether the slightly greater growth obtained with 1 $m\mu$ of compounds #510, #511 and #1029 is significant.

pyridine ring instead of a hydroxymethyl radical (table 4).

Compounds #510 and #511 were used in a second experiment with 1, 10 and 50 μg. per flask in the presence of 10 μg. of thiamin. The inoculum was from roots which had grown for twenty-eight passages in a solution supplemented with thiamin. Neither benefit nor injury was observed with either compound.

Compound #1797 which differs from pyridoxine in having a methyl instead of a methoxy radical in the fourth position was not found to replace pyridoxine. It was used both filtered sterile and autoclaved. Up to 50 mμ moles per flask it was neither beneficial nor detrimental.

Compound #3882 differs from pyridoxine by having an ethyl instead of methyl radical in the second position on the pyridine ring. Pfeffer's solution containing 1 per cent cane sugar instead of the 2 per cent used in the other experiments reported in this

paper was used with this compound. It was an effective substitute for pyridoxine (table 3); in fact 1 mμ mole per flask was more effective than an equivalent amount of pyridoxine. In the experiment reported in table 3, fragments of roots which had grown for forty-nine successive passages in Pfeffer's solution supplemented with thiazole were used as inoculum, and the experiment ran from June 11, 1941, to August 7, 1941.

The experiment was repeated using as inoculum fragments of roots which had grown for fifty-five successive passages in Pfeffer's solution supplemented with thiamin. The roots were grown from July 5, 1941, to September 4, 1941, and the results were similar to those of the first experiment.

The chemical structure and results obtained with excised tomato roots as well as those reported by Unna (1940) for rats, are summarized in table 4.

DISCUSSION.—In general the results obtained on the effect of the pyridoxine analogues on excised to-

mato roots agree with their effects on dermatitis of rats as reported by Unna (1940). He found the diacetate and triacetate as active on rats as pyridoxine. Bohonos, Hutchings and Peterson (1941) found the diacetate active for *Lactobacillus lactis*, but the triacetate was inactive. It is probable that the acetates dissociate in solution yielding free pyridoxine. Unna found compound #1442 slightly active (about 2 per cent the activity of pyridoxine), #1030 about 10 per cent as active and #1032 less than 2 per cent as active as pyridoxine.

Möller, Zinna, Jung and Moll (1939) reported compound #1797 to have about 2 per cent the activity of pyridoxine on *Streptobacterium plantarum* (*Bacterium acetylcholini*), though Unna found it to be inactive for rats. No activity of these substances was observed for excised tomato roots. However, a small activity such as 2 per cent or 10 per cent might not have been detected with excised tomato roots under my experimental conditions. For example, compound #1030 was toxic to excised tomato roots in amounts which would have been effective if it had one-tenth the activity of pyridoxine, and compounds #1442 and #1032, which showed 2 per cent or less of the activity of pyridoxine for rats, might have evidenced activity for tomato roots in amounts of 500 mμ moles. Of particular interest is the activity of compound #3882 which was as effective, or even more effective, for excised tomato roots than pyridoxine. Unna, as reported by Harris and Wilson (1941), found this compound to have on rats less than 2 per cent the activity of pyridoxine. It would

be of interest to determine its activity on other organisms.

It appears clear from the results obtained with excised tomato roots in these investigations and those obtained by others with rats, lactic acid bacteria and *Streptobacterium plantarum* that pyridoxine has a high degree of specificity. The results obtained with the effect of the various pyridine derivatives as compared with that of crystalline synthetic pyridoxine indicate that acetylation of pyridoxine did not reduce its activity for excised tomato roots. Methylation or ethylation of one of the hydroxymethyl groups, methylation of the phenolic hydroxyl groups or replacement of one or more hydroxymethyl groups by methyl or amino groups reduced the vitamin activity materially or destroyed it entirely.

SUMMARY

The effect of twelve analogues of pyridoxine on the growth of excised tomato roots in the presence of thiamin was studied. Acetylation of pyridoxine had no influence on its beneficial action and the substitution of an ethyl for the methyl group in the second position on the pyridine ring did not reduce the activity. The other nine analogues were inactive. Pyridoxine has a high degree of specificity for the growth of excised tomato roots.

WOOD STRUCTURE OF THE NATIVE ONTARIO SPECIES OF JUNIPERUS¹

M. W. Bannan

JUNIPERUS is represented in Ontario by three species. *J. communis* var. *depressa* Pursh is widely distributed, *J. horizontalis* Moench has a more or less similar range but is usually less common, and *J. virginiana* L. is limited to certain areas in southern Ontario. As is well known, the three species are of diverse habits. *J. horizontalis* is creeping with most of the branches and stems flat on the ground, *J. communis* var. *depressa* generally forms large mats with the proximal portions of the branches or stems more or less prostrate and the distal parts semi-upright, and *J. virginiana* is arborescent.

MATERIAL.—Specimens of branch and stem wood of *J. communis* var. *depressa* were gathered from various localities in southern Ontario but principally from old pasture land near Brighton, stony soil in the Kawartha Lakes region, on rocks in the Parry Sound district, and from a sand dune area near Inverhuron on Lake Huron. The latter site also provided most of the *J. horizontalis* material which was kindly collected for the writer by Dr. Kathleen and Mr. Donald Hull. Supplementary material came from the Lake Superior area and from Bruce peninsula. Collections of *J. virginiana* were more complete and consisted of the following: stems, branches, and rooted branches of mature trees growing in a dune area on the shore of Lake Ontario south of Brighton; stems and roots of mature trees growing in shallow stony soil overlying limestone in the area east of Picton; small trees on a gravelly hillside, and branches and stems of mature trees growing in stony soil in an adjoining level area north of Trenton; and small trees and the branches, stems, and roots of mature trees in a clayey soil east of Beamsville in the Niagara peninsula.

Only stem and branch wood of *J. communis* var. *depressa* and *J. horizontalis* was examined, but in the case of *J. virginiana* the studies were extended to in-

clude such parts of the tree as indicated in figures 1-8. Here the term "stems small trees" denotes the inner wood 1-3 mm. from the pith at the base of the stems of young trees 0.5-1 m. tall. In the case of branches only those growing on mature trees were used, and both the inner wood 1-3 mm. from the pith and the outer wood on the upper and lower sides 1-3 cm. from the pith were sectioned. The term "stems large trees" refers to the wood in the periphery of old stems 2-4 dm. in diameter. All roots collected were lateral roots located at distances of 1.5-3 m. from the bole of mature trees. Both the inner wood 1-3 mm. from the center and the peripheral wood 1-3 cm. outward were studied.

The root habit of *J. virginiana* evidently varies with the environment. Bunker and Thomson (1938) recorded roots at a depth of 24.5 feet in the Oklahoma panhandle area. Small trees up to a meter tall excavated by the writer from deep gravelly soil had strong tap roots extending in some instances to depths of nearly a meter. Most of the larger trees from which root samples were taken were, however, growing in very shallow soil overlying limestone, and here the root systems were necessarily flat and plate-like. No deep roots were available for study. In the Abietineae these were found to differ materially in their structure from lateral roots near the surface (Bannan, 1941a). The data in figures 1-8 refer only to lateral roots in the top 1-2 dm. of soil.

The data in figures 1-8 are based upon a study of approximately one hundred specimens of *J. virginiana*. In each figure the maximum average (i.e., the average in the specimen with the largest elements) is shown by the upper broken line, the grand average for all specimens by the middle solid line, and the minimum average (in the specimen with the smallest elements) by the lower broken line. The descriptions which follow apply only to *J. virginiana* unless

¹ Received for publication November 24, 1941.

otherwise stated, but in no important details was the wood in the other two species materially different.

TRACHEID SIZE.—The average size of the tracheids in different parts of the tree is shown in figures 1 and 2. The values here presented were determined from the early-wood tracheids in the growth rings and indicate the external dimensions of the cells from one middle lamella to the next. The determinations

were made from transverse sections and included both wide and narrow cells as they appeared in these sections. Hence the values for the tangential width are somewhat less than would have been obtained had only the central widest part of each tracheid been measured from tangential sections.

The general trends in size of tracheids in different parts of the tree were similar to those noted in *Thuja occidentalis* (Bannan, 1941c). The size increased outward from the center in stems and branches, and was much greater in most lateral roots than in the aerial parts of the tree. In the case of roots, however, the tracheid dimensions varied with conditions under which the roots were growing. Lateral roots in more or less uniform soil had the largest cells, whereas in roots wedged between stones the tracheids were small and thick-walled with late wood sometimes constituting a large proportion of the growth rings. The wood in these roots was of fine texture and had a stemlike aspect.

TRACHEID PITTING.—The intertracheary bordered pits on the radial walls varied considerably in size in different parts of the tree. The largest pits were found in the early wood of the growth rings in lateral roots where the diameter ranged from 12–18 μ with the average about 15 μ . In the outer wood of old stems the pits were on the whole slightly smaller, and in the inner wood of branches and young stems the usual range was from 7–10 μ , the average 8–9 μ . In all parts of the tree the size tended to decrease from the early to the late wood in the growth rings.

The pits were generally uniseriate, but occasionally biseriate arrangements occurred in the early wood of the growth rings, especially in the outer wood of old stems and throughout lateral roots. In the latter case the pits were usually opposite, rarely alternate. Crassulae were variable and ranged in shape from straight to curved and in degree of development from distinct to absent.

Unlike *Thuja occidentalis*, the torus was well developed in most pits and was generally larger than the pit aperture. In lateral roots the margin of the torus was, as a rule, finely serrate (fig. 9), but in some cases was very irregular in outline with conspicuous bands or arms extending to the edge of the pit chamber. This irregularity was even more marked in branch and stem wood (fig. 10 and 11).

Tangential pitting occurred characteristically in the late-wood tracheids, rarely in the early wood. In the latter case it was usually associated with injury or some other abnormality in the wood.

The number of pits per crossing field between tracheids and ray cells was exceedingly variable, varying from cell to cell, with position in the growth ring, part of the tree, size and shape of the ray cell, and size of the tracheid. In general the number of pits decreased from the early to the late wood in the growth rings, was greater in roots than in stems or branches, and decreased from the inner to the outer wood in both aerial and subterranean parts of the tree (fig. 3). The range in the average number of pits between early-wood tracheids and ray parenchyma cells of

Fig. 1-8. *Juniperus virginiana*. Variation in different parts of the tree.—Fig. 1. Radial diameter of tracheids in early wood of growth rings.—Fig. 2. Tangential diameter of tracheids.—Fig. 3. Number of pits per crossing field between tracheids and ray parenchyma cells.—Fig. 4. Size of pits in crossing field.—Fig. 5. Height of ray parenchyma cells.—Fig. 6. Ray height in cells.—Fig. 7. Number of rays per sq. mm. of tangential section.—Fig. 8. Width of ray cells in tangential section.

normal radially elongated outline was from 3.4 in the inner wood of roots to 1.7 in the outer wood of old stems. The trends resembled those observed in *Thuja occidentalis* but the numerical values were about 50 per cent lower.

The diameter of the crossing-field pits also varied greatly, both within the same field and in different parts of the tree. On the whole the largest pits occurred in lateral roots and the smallest in the inner wood of branches and stems (fig. 4). As in *Thuja occidentalis* the size tended to increase outward from the center in stems and branches, and to decrease slightly outward from the center in roots. The average values were closely similar to those in that species.

The pit apertures in the crossing fields of the early-wood tracheids were usually slitlike with the inclination ranging from almost horizontal to steep. The size and outline of the aperture was variable and no definite trends were discovered in different parts of the tree.

XYLEM PARENCHYMA.—These cells ranged from plentiful to scarce. Their arrangement varied from widely scattered to compact tangential series, with tangential alignments predominating. No correlation was discovered between frequency of occurrence or distribution and position in the growth ring or location in the tree. The transverse walls varied from slightly thickened to very thick and strongly beaded. The thinner walled cells occurred most often in roots (fig. 12 and 13) and the thickest in stems (fig. 14–16), but there was much variation even within a single specimen.

SIZE AND DISTRIBUTION OF RAYS.—In general the trends in width, height, and distribution of rays in *J. virginiana* were similar to those recorded for *Thuja occidentalis* (Bannan, 1941c). Nearly all the rays were one cell wide, but a few, representing only a small fraction of one per cent, ranged from partially biseriate to multiseriate. The height varied from one to a maximum of thirty-two cells, the latter height being observed in the outer wood of an old stem. The average height varied greatly, both from specimen to specimen and in different parts of the tree. As in *Thuja* the greatest variation was noted in the periphery of old stems, where the range in average height was from 2.3 cells in one specimen to 4.5 cells in another with a grand average of 3.4 cells for all. The average height tended to increase from the inner to the outer wood in both stems and roots (fig. 6), and was slightly higher in roots than in stems or branches of similar size. The distribution of rays was also highly variable, but as a rule the rays were most numerous in the inner wood at the base of young stems and least frequent in the peripheral wood of old stems and throughout the wood of lateral roots (fig. 7). The rays in *J. virginiana* were noticeably more numerous than in *Thuja occidentalis*, the average distribution in different parts of the tree ranging from 91 to 155 rays per sq. mm. in the former as compared with a range of 53 to 87 in the latter.

The size and shape of the ray cells differed with position in the ray, location in the annual ring, and part of the tree. The cells in the first-formed parts of the rays were often vertically extended, whereas those in the succeeding parts were usually radially elongated. As a rule the latter cells were longer in the early wood of the growth rings than in the late wood. The height of these typical radially elongated ray cells tended to decrease from the inner wood toward the periphery and to be at a maximum in roots (fig. 5). The tangential width of the cells was also greater in roots than in other parts of the tree (fig. 8).

As stated above most of the rays were uniseriate throughout, but exceptional ones became multiseriate. Stages in the widening of such a ray are illustrated in figures 17–23. The ray began at the pith (fig. 17) and in the first few growth rings resembled ordinary rays in width and in size and shape of the ray cells (fig. 18). In the tenth ring, however, while the ray was still uniseriate, the cells became noticeably wider (fig. 19), and this increased width was maintained until the twenty-first ring (fig. 20). Here the ray widened to two cells and continued biseriate until the thirty-second ring (fig. 21–23), after which there was rapid expansion. A short distance farther out the ray connected with an adventitious root.

Sometimes the development differed in certain respects from that described above. Although the majority of the unusual rays originated in the vicinity of the pith, a few began in the secondary xylem. In some cases there was enlargement of the cells while the ray was still uniseriate, whereas in other instances no appreciable alteration in size or shape could be detected, the ray resembling an ordinary uniseriate ray up to the point of widening. The actual broadening was sometimes gradual, extending through several growth rings, while in other cases it was so sudden that the ray seemed to flare out like a funnel. After having widened some of the rays connected with adventitious roots, some were abruptly succeeded by several smaller rays, and others gradually narrowed. For instance one ray broadened to several cells, then was followed by smaller rays two of which underwent the following changes: one widened, then narrowed, widened again, split into smaller rays, one of which widened and connected with an adventitious root; the other widened, subsequently narrowed, widened again, was succeeded by smaller rays, and one of these widened and in turn was broken into smaller units.

As in *Thuja occidentalis* ray widening appeared to be due to subdivision of ray initials and gradual narrowing to failure of some of the initials to continue normal tangential division. Where the wide rays were abruptly succeeded by uniseriate rays the appearance in transverse sections was generally suggestive of a subdivision of the ray by penetration of fusiform elements between the ray initials. At times, however, some of the uniseriate rays were separated from the preceding wide ray by gaps equal to the width of a few tracheids. Whether the ray initials

here involved were of recent origin or were old initials that had merely ceased normal division for a short time was not determined.

These unusual rays were very rare. None were discovered in old stem wood. In more than twenty small branches 0.5–1 cm. in diameter, collected from several sites, the average occurrence was only one in every 10 sq. cm. of tangential area. In the outer wood of old branches 2–5 cm. in diameter the average was one per 2.3 sq. cm., and in the wood of small trees 0.5 to 1 m. tall it was one ray per 1.7 sq. cm. The distribution was exceedingly erratic. For instance, two-thirds of the unusual rays noted in the thirteen old branches examined were in one specimen. The rays were sporadic in branches collected in the Niagara peninsula, but none were observed in six specimens cut from trees growing in the dune area near Brighton. Similarly in the case of the small trees three times as many rays were found in the Niagara material as in that obtained near Trenton in eastern Ontario.

RAY STRUCTURE.—Ray tracheids occurred only rarely in the various stems, branches, and roots examined. They were sporadic in both the ordinary uniseriate rays and in the unusual rays described above. When present in the ordinary rays they were located in or near the first-formed part where the ray was usually only a single cell high, although sometimes such new rays coalesced with older rays nearby and formed marginal rows along their upper or lower side. The number of ray tracheids in each new ray was never great, generally only a cell or two. The proportion of new rays containing tracheary cells was highly variable, ranging from a high percentage in some cases to very low in others. Counts were made of the number of ray rows containing ray tracheids and in most cases the proportion of such rows was less than 1 per cent of the total number of the rows in all the rays (new and old). The range was from 3 per cent in one specimen to nearly zero in most. No outstanding differences were noted between roots, stems, or branches.

The occurrence of ray tracheids in the unusual rays was also sporadic. The majority of these rays were parenchymatous throughout, but occasionally ray tracheids were interspersed among the parenchyma cells, both in the uniseriate and wide portions of the ray. When in the narrow parts, the ray tracheids were generally rectangular in shape and smooth-walled; whereas those in the wide portions were more varied in shape, and the walls sometimes had reticulate thickenings on the inside. When these rays connected with adventitious roots, gradations were observed from such reticulate cells to primary xylem tracheids in the newly formed root. As a rule tracheary cells were less frequent in the unusual rays in stem and branch wood of *J. virginiana* than in the comparable rays in *Thuja occidentalis*. Irregularity in cell shape, both of the parenchymatous and tra-

cheary cells, was also less marked. On the whole there was closer resemblance between the unusual rays in branch wood of *Juniperus* and root wood of *Thuja* than between the rays in branch wood of the two genera.

The structure of the parenchyma cells in typical uniseriate rays, especially that of the tangential walls, has been frequently described. Because the tangential wall is thicker and, hence, the recessions in it are deeper than in most Cupressineae, the thin areas have long been known as "juniperoid pits." Bailey and Faull (1934), however, state that these are not true pits but are deeply depressed pit-fields in a thickened primary wall. In material examined by the writer the tangential walls varied greatly, but on the whole the most prominently thickened or beaded walls occurred in the branches and the thinnest in the inner wood of lateral roots. In the latter the tangential walls ranged from strongly to only sparsely or delicately knobbed, and on rare occasions were nearly smooth. The horizontal walls were also variable, the combined thickness of the walls of the two adjoining ray cells ranging from 1.5–3 μ , with the thinner walls occurring most often in roots and the thicker most often in branches. As a rule the pit-fields were comparatively widely spaced but sometimes were approximate. Indentures, or recessions, in the horizontal wall adjoining the vertical wall were usually prominent, as Peirce (1937) has stated, but in occasional cells were absent.

Parenchyma cells in the unusual rays showed a greater range in structure, particularly in the wide portions of these rays. Gradations were observed from cells with thick heavily lignified walls on all sides to those with uniformly thin unlignified or only slightly lignified walls. Some of the cells were living, others dead, the proportion of the latter tending to increase as the ray widened.

RAYS AND ADVENTITIOUS ROOT FORMATION.—A formation of adventitious roots was observed in all three species of *Juniperus*. The freest development was noted in *J. communis* var. *depressa* and *J. horizontalis* where roots were formed along the lower sides of the decumbent branches. In the case of *J. virginiana* there was less opportunity for such rooting to take place owing to the arborescent habit of the species, and to the nature of the sites in which the trees usually grew. Most of the trees in the areas visited had lost their lower branches, but, where these were still living and were in contact with the ground, conditions did not favor rooting. The soil was usually stony with sod between the stones, so there was little chance for loose earth to collect around the branches, and the natural deposition of organic litter under the trees never seemed heavy enough to bury any of the branches. It was only in dune areas, where the lower parts of the bole and the proximal portions of the lowermost branches were covered by the shifting sand, that root development was ob-

Transverse sections of branch wood showing steps in development of unusual ray and its connection with an adventitious root.—Fig. 27. served. Here branches which had been buried for some time produced many adventitious roots (fig. 30), and in some cases these evidently made a considerable contribution to the growth of the branches, for the latter were much larger in and above the rooted areas than in the proximal portions between the roots and the stem. For instance in the branch illustrated in figure 30 the cross-sectional area just above the rooted portion was approximately 3 times that of the proximal part adjoining the stem. The branches were usually bowed, turning from a more or less horizontal direction near the stem to an upright

In *J. communis* var. *depressa*, as in *J. virginiana*, all the adventitious roots examined connected with xylem rays. This relationship is illustrated in figures 24-26. The ray began at the pith (fig. 24) and in the inner two growth rings was uniseriate and composed exclusively of parenchyma cells resembling those in ordinary rays. In the third and fourth rings the ray cells widened somewhat, and in the fifth ring the ray became biseriate. Further broadening took place in the next three rings (fig. 25), after which the ray was succeeded by smaller units, one of which widened again in the thirteenth and fourteenth rings where a

Fig. 28-30.—Fig. 28. Dune area showing in center a tree of *J. virginiana* whose lower branches have rooted and turned upright, and in the lower right *J. communis* var. *depressa*.—Fig. 29. Portion of branch of *J. communis* var. *depressa* showing partially formed roots.—Fig. 30. Buried portion of branch of *J. virginiana* showing profuse development of adventitious roots.

position farther out. Because of this upright habit and of the increase in growth which sometimes made the branches almost as large as the stem, the branches together with the stem could easily be mistaken at a distance for a group of separate trees (fig. 28).

In all the specimens of *J. virginiana* studied the adventitious roots connected with rays in the xylem. Seven of the rays were traced to their point of origin, and it was found that six began at the pith and one in the early wood of the second growth ring. All seven rays were initially uniseriate and resembled other rays in the xylem, but later were distinguished by gradual or abrupt broadening, sometimes preceded or accompanied by enlargement of certain of the ray cells as described above in the account on ray structure. In some instances the root was formed soon after the broadening had taken place, in other cases the ray repeatedly widened and narrowed or was succeeded by smaller rays before the final broadening and ultimate root formation were accomplished.

root was initiated (fig. 26). Some thirty-nine rays associated with root development were studied, and of these twenty-nine began at the pith and the other ten at various points in the secondary xylem from the first to the third growth rings. All were uniseriate at first, but in their subsequent development they differed considerably. Some widened gradually, others abruptly. Some connected directly with roots after the first extensive widening; others split up into small rays, certain of which in turn widened and ultimately connected with roots. The locations in the wood at which ray widening and root formation took place were inconstant, even in the same piece of branch. Some of the rays were exclusively parenchymatous (fig. 27), but in other rays varying numbers of ray tracheids were interspersed among the parenchyma cells both in the uniseriate and wide portions of the rays. On the whole these tracheary cells were more frequent than in *J. virginiana*.

The unusual rays were observed in the upright aerial portions of the branches as well as in the

buried parts. They were never numerous but usually occurred more often than in *J. virginiana*, the average distribution in several specimens collected from various points in southern Ontario being 1.2 rays per sq. cm. of tangential area. Although the rays were found throughout the length of the branches, functioning roots were formed only where the branches were in contact with the ground or were covered by soil. In a few cases small protuberances appeared on the lower sides of the aerial parts of the branches (fig. 29), and sectioning revealed these to have a structure resembling the initial stages of root formation. They appeared to be roots which had developed only far enough to bulge the bark but not break through it. These roots, like the functioning roots, connected with rays in the xylem which were generally of the unusual type. A similar relationship was described for *Thuja occidentalis* (Bannan, 1941b). In *J. communis* var. *depressa* these partially formed roots were exceedingly sporadic, being completely lacking on some branches and quite numerous on others (fig. 29). For instance, on the lower side of one branch there were as many as six or seven to the sq. cm. at distances as much as 0.5 m. above the ground. The ground was in sod, and there was no evidence to indicate that the parts of the branch bearing the arrested roots had been covered by soil or litter within the last few years when the roots were initiated.

In *J. horizontalis* the creeping branches rooted freely and all the roots studied were associated with xylem rays similar to those described for the other two species. Twenty-four of the rays traced to their origin extended to the pith, whereas twenty-three began at various points in the secondary xylem from the first to the fourth growth rings.

DISCUSSION.—Many of the trends in anatomical variation in *Juniperus virginiana* resembled those observed in *Thuja occidentalis*. Similar tendencies were noted particularly in such quantitative characters as size of the tracheids, size of the intertracheary pits, size and number of pits per crossing field between tracheids and ray cells, height and distribution of rays, and size of ray cells. In some cases the actual numerical values for the average and range of variation were similar in the two genera; in other cases they differed only slightly, but in one or two characters, as, for instance, the frequency of the rays, the average values were markedly different. Even in the latter case, however, the variation in different specimens was such as to render of doubtful value the use of this character for diagnostic purposes.

Certain of the anatomical characters more often regarded as diagnostic also varied considerably, although in some cases trends could be detected in different parts of the tree. For example, the tangential walls of the ray cells long considered to be a diagnostic feature of *Juniperus* wood, were usually strongly thickened and knobbed, but in roots particularly were highly variable, ranging from thick in most cells to thin and only weakly or sparsely beaded in others, and were on the whole definitely thinner

than in branch wood. The horizontal walls of the ray cells were usually comparatively thick with rather widely spaced pit-fields, but here again there was much variation, especially in roots where the walls tended to be thinner than in branches. The transverse walls of the xylem parenchyma cells were likewise variable, with the thinner walls occurring most often in roots and the thicker in branches or old stems. In *Thuja occidentalis*, on the other hand, no such tendency was observed, the walls of the parenchyma cells were variable in all parts of the tree without being noticeably thinner or thicker on the average in any one part. Because of lack of information on the trend and range of structural variability in most of the Cupressineae, no attempt will be made at this time to select particular characters which might prove useful for the identification of *Juniperus* wood or its separation from that of other genera.

Unusual rays resembling those reported for *Thuja occidentalis* occurred in all three species of *Juniperus*. In the latter these rays were generally more infrequent than in *Thuja*, and they usually contained fewer interspersed tracheary cells, but the distribution and structure were much too variable in both genera to have diagnostic value.

In *Juniperus*, as in *Thuja*, adventitious roots arising from stem or branch wood connected with rays in the xylem which were almost always of the unusual type mentioned above. Whether such relationship is general for the Cupressineae cannot be stated. Preliminary investigations indicate that different relationships obtain in certain other conifers, notably the Abietineae. In the rooted branches of *Abies* and *Picea* examined to date the roots originated from hitherto dormant buds, and in the few available specimens of *Larix* the roots arose from dwarf (leaf-bearing) branches.

SUMMARY

Many of the trends in anatomical variation in different parts of the tree in *J. virginiana* resembled those observed in *Thuja occidentalis*. Similar tendencies were noted in such characters as size of the tracheids, size and distribution of the intertracheary pits, size and number of pits per crossing field, height and distribution of rays, and size of the ray cells.

Other features usually regarded as valuable for purposes of identification such as the thickness and character of the walls of the ray and xylem parenchyma cells also varied considerably. Because of such variability it is clear that the selection of characters which will ultimately prove diagnostic must be held in abeyance until there is more complete knowledge of the range of variation in related forms.

An expansion of certain of the rays to a multiserial condition, such as observed in *Thuja occidentalis*, was also noted in all three local species of *Juniperus*. All adventitious roots arising from stems or branches connected with rays in the xylem, nearly always of this unusual type.

THE DISTRIBUTION AND PREPARATION OF CITRUS PEROXIDASE¹

W. B. Davis

SZENT-GYÖRGYI (1928), citing Onslow (1921), speaks of the orange, grapefruit and lemon as typical "peroxidase plants," but apparently failed to find active peroxidase in the juice of the citrus fruits mentioned. The flesh and peel of the citrus fruits do not darken quickly on injury as does the flesh of potatoes, apples and many other fruits. According to Huszák (1937), ascorbic acid has so commonly accompanied peroxidase that some workers suspect that it is a part of the peroxidase system. Citrus fruits are well known for their ascorbic acid content. Although orange juice slowly darkens on storage, no striking change in color is noted when it is exposed to the air a short time. Wilson (1928) has suggested that the Maillard reaction is responsible for this change, which, however, is possibly due to other causes. Orange residues accumulating in the manufacture of by-products sometimes turn black. Willmott and Wokes (1926) made qualitative tests on the peel of citrus fruits.

While the above brief literature survey indicates that peroxidase should be found in citrus fruits, apparently little work is available to show this is actually the case.

This paper was written to prove the existence, and point out the distribution, of peroxidase in some citrus fruits and to describe some of the attempts to make a crude preparation of this enzyme. The properties of citrus peroxidase will be described in another paper.

DISTRIBUTION OF PEROXIDASE.—A preparation of citrus peroxidase was needed for work dealing with citrus juices. Since the peel of those citrus fruits which have an appreciable layer of albedo gives a strong reaction with guaiacum and hydrogen peroxide, an attempt was made to isolate peroxidase from Navel orange peel, which is quite thick. A slight modification of the alkaline extraction method of Willstätter was tried with unsatisfactory results. It appeared from later determinations that extracts from orange peel have little power to catalyze the

oxidation of pyrogallol by hydrogen peroxide. This experience with the peel led to a systematic search of the different tissues of available citrus fruits to find where peroxidase was located. The quantitative method of Balls and Hale (1933) was used. In this method the quantity of hydrogen peroxide used in the oxidation of pyrogallol is measured by titration with standard thiosulfate. The catalysis by peroxidase takes place at 30°C. and at pH of 8.00. The peroxidase values obtained by this method differ from the values obtained by the method of Willstätter and Stoll because of the difference in pH and temperature between the two determinations. One important feature is that peroxidase may be estimated in material containing catalase. The peroxidase units (P.U.) given in this paper are the same as the units described by Balls and Hale (1933). Results are shown in table 1.

Large quantities of peroxidase were not found in the tissue of any of the citrus fruits previously examined, except in the outermost layer of the peel of grapefruit. Tangerines, which became available at this stage of the investigation, were examined and appeared to have a greater content of peroxidase, particularly in the seeds, than any other citrus fruit previously examined. A detailed examination of the seeds revealed a high peroxidase activity in the inner coat. But the end of the seed opposite to its point of attachment to the fruit, the chalazal end, where the inner seed coat is thickened, contains very little peroxidase. The inner coat of some tangerine seeds darkens when left in contact with the crushed pulp for twenty-four hours. The outer seed coat appears to have little peroxidase activity.

In addition to the examinations of fruits mentioned in table 1, others were made of a variant of grapefruit called "Seedy" and of green Valencia oranges.² The Seedy grapefruit is of interest, not only on account of its high peroxidase content in the inner seed coat (as high as 1,436 P.U. per kilo), but also on account of the larger number of seeds per fruit; the supply of these fruits is, however, limited. The inner seed coat (not including the thickened chalazal end)

² Thanks are due to Mr. A. D. Shamel for calling attention to the Seedy grapefruit, and to Mr. Brown on whose ranch the fruit was grown.

Cotyledons	*	27.6	*	55.2

** = No analysis made.

of the seeds of immature Valencia oranges ran 1,220 P.U. per kilo.

The approximate peroxidase content of different tissues varies considerably, perhaps according to the age, locality where grown, and storage conditions. The moisture content of the different tissues also varies. The separation of inner and outer flavedo is an arbitrary matter. By the outer flavedo is meant the thinnest layer that can be pared from the outside of the fruit. This tissue includes but a small proportion of the oil cells.

As may be seen from table 1, the localized portions of citrus fruits, particularly of their inner seed coats, have high peroxidase activity. With regard to their peroxidase activity, these citrus fruit tissues are high in comparison with malt sprouts and horseradish (550 and 403 peroxidase units per kilo, respectively, according to Balls and Hale [1933]), the same method being used for all determinations.

PREPARATIONS.—To determine the best of a few peroxidase extractants, about one gram of inner seed coats of tangerines, grapefruit and lemon were mixed together and ground in a mortar with ether to a fine powder. Aliquots of this powder were again ground with the different extractants shown in table 2. The centrifuged extract was used for quantitative determinations. The loss of peroxidase activity after storage of the extract at 4°C. for forty-eight hours

is also shown. While ammonium sulfate and sodium bicarbonate were better extractants than phosphate buffer at pH 8, the latter proved to be more useful because an acetone precipitate separates easily from it.

Various attempts were made to prepare peroxidase from the inner seed coats removed by hand. In one case 84 grams of inner coat of tangerine seeds testing 920 P.U. per kilo (a total of 77.28 units) were disintegrated in 300 ml. M/20 phosphate buffer at pH 8 in a Waring blender (Davis, 1939) at 3 to 4°C. Acetone was added to the liquid after it was squeezed through muslin by hand, until a precipitate occurred. The precipitate dried with ether weighed 1.334 grams. The activity was 18,400 P.U. per kilo of precipitate (a total of 24.55 units). The recovery was 29.34 per cent. In another case 33 grams of inner seed coat of lemon, testing 661 P.U. per kilo, were extracted with 2 per cent ammonium sulfate and the enzyme was precipitated by saturation of the extract with ammonium sulfate. The precipitate (1.5 grams) had 6,700 units per kilo, or a total of 10.0 units. This was 45.85 per cent of the original 21.8 units. A preparation of high activity has not yet been obtained from grapefruit flavedo.

Since only approximately 5 to 7 per cent of the seed of citrus fruits is inner coat, the accumulation of a large quantity of this material is a difficult matter.

TABLE 2. *Relative effectiveness of various extractants for removing peroxidase from inner seed coats.*

Extractant	Peroxidase units extracted per kilo of fresh tissue	Loss of activity after 48 hours storage at 4°C.
		Per cent
Distilled water	783	4
M/20 phosphate buffer, pH 9	1,207	6
M/20 phosphate buffer, pH 8	1,643	7
2 per cent sodium bicarbonate	1,765	13
2 per cent ammonium sulphate	1,835	13

Some method of getting sufficient quantities for large-scale operation was sought. While tangerine seed was not available in quantity, lemon seed was secured in twenty-five pound lots.² The separation of peroxidase from the ground mixture, consisting of both seed coats, is difficult on account of the slimy substance (apparently pectin) in the outer coat which makes up the bulk of the mixture. Therefore, the inner coat was largely separated from the outer by the following process. First, most of the cotyledons were removed by crushing the dry seed between rollers and screening. Then the inner coat was loosened from the outer in a ball mill, and the lighter inner coat particles were separated from the outer by again screening in a current of air from a fan. The bran thus separated and containing a small proportion of outer coat and cotyledons was extracted with petroleum ether to remove oil. In this way, 600 grams of bran was prepared.

Two hundred and fifty grams of this bran, containing 47.8 units of peroxidase, were extracted with 2 per cent ammonium sulfate at 4°C. for about twenty

² The cooperation of Mr. H. W. Hall of the Lemon Products Company of the California Fruit Growers Exchange in separating these seeds is acknowledged.

hours in the cold. The filtered extract was saturated with ammonium sulfate, and again filtered. In the precipitate 20.55 units were recovered, thus giving a recovery of approximately 43 per cent. However, the preparation contained only 736 peroxidase units per kilo of precipitate, requiring further purification to reach the activity of preparations made from hand-removed inner coat.

SUMMARY

The distribution of peroxidase in different tissues of orange, grapefruit, lemon and tangerine is described, and the high activity in the inner seed coat of these fruits, especially tangerines, is pointed out. Hand-removed seed coats gave the highest activity in crude preparations. That it may be possible to make peroxidase on a large scale is indicated from experiments with lemon seeds, which are available in quantity.

SOME FEATURES OF THE STRUCTURE OF ARCTOSTAPHYLOS VISCIDA¹

Bernice E. Doyel

ARCTOSTAPHYLOS is a genus of Ericaceae including erect, evergreen shrubs, some of which attain a height of twelve feet or more. The branches are crooked with a red, glabrous bark. The alternate leaves, which vary greatly in size, are generally elliptical and are often sharply mucronate. For the most part they are glabrous and grey-green, although the degree of color differs with the species; many are recurved. The scaly axillary buds begin to unfold late in spring (statements here given as to the seasons or months at which stages are reached apply to the species in southwestern North America; not necessarily to those which are not). These buds quickly give rise to stems a few centimeters long and bearing perhaps a dozen leaves. Most of these annual shoots terminate in panicles which remain dormant until fall; the form of the resting panicle is characteristic of the species (Weislander and Schreiber, 1939). The flower buds,

in the axils of bracts and embraced between pairs of bractlets, are recognizable late in spring. After the first rain of the season the flowers start to swell; the pedicels, beginning to elongate, carry them beyond the protection of the bracts and bractlets. The blooming season is generally from December until February. The pedicels of the flowers and fruits of some species are covered with minute, glandular hairs. Because of the presence of these hairs the inflorescence is sticky to the touch. The flowers range from white to light pink in color; they are hermaphroditic and ordinarily pentamerous. The sepals are separate, recurved at the tips, and finely ciliate. The petals are united to form a urceolate corolla; the tips of the petals curve outward. The stamens are twice the number of petals and are attached to the bases of the petals. Each anther bears a pair of recurved appendages and dehisces through two pores. The filaments are ribbon-like with expanded bases; the bases

¹ Received for publication November 26, 1941.

are hairy, the upper portions smooth. The stamens in the planes of the petals are definitely longer than those in the planes of the sepals. The base of the ovary is surrounded by a glandular disk. All parts of the pistil are glabrous in some species; the ovary is glandular in others. The lobed stigma extends above the corolla in the open flower. In many cases the stigma and style continue to be attached after the ovary has developed into a young fruit. The ovary is superior and is divided into from four to ten cavities. Each cavity contains one epitropous ovule. The red fruit, smooth or glandular, is subglobular and depressed at both ends. The seeds are enclosed in nutlets which may be separate, or a number or all of them may be united into one.

The characters as given exclude from this genus several segregates (*Comarostaphylos* Zuccarini; *Arctous* Niedenzu; *Xylococcus* Nuttall; *Ornithostaphylos* Small; and *Schizococcus* Eastwood; cf. Small (1914) and Eastwood (1934a)). Thus limited, the genus includes fifty-three species, according to the latest monograph (Eastwood, 1934b), to which may be added *A. cratericola* Donn. Sm., making fifty-four.

The distribution is circumpolar with an extension southward in western North America to Central America; the greatest development of species is in California where it makes up a large percentage of the abundant chaparral.

The observations presented in this paper were made upon *Arctostaphylos viscida* Parry (1887). This species is distinguished by shrubby stature, grey leaves, a slender and recurved nascent inflorescence, the cauline part of the panicle (rachis and pedicels) glandular, ovary (and fruit) glabrous. Parry gives no definite type locality; the species has been found in the foothills of the Sierra Nevada from Tulare County northward to Jackson and Josephine Counties, Oregon, and thence southward in the coast range to Lake County.

The material used was collected at Mormon Island in El Dorado County by Dr. Herbert F. Copeland. Collections were made at intervals of two weeks during the 1939-1940 season of development and again in the spring of 1941. Bouin's fluid was used for killing and fixing the earlier material; in the later collections FAA was also employed. All the slides were stained with a triple combination of safranin, light green, and aniline blue.

It is with gratitude and appreciation that I acknowledge the generous help and unfailing interest extended to me by Dr. Copeland. I am also indebted to him for figures 1, 2, 10, and 11.

VASCULAR ANATOMY OF THE FLOWER (fig. 5).—The vascular supply in stem, rachis of panicle, and pedicel of *Arctostaphylos* is arranged in a typical siphonostele. After the vascular tissue enters the receptacle of the flower it breaks up into a number of whorls of bundles which continue up into the flower and supply its various parts. The first whorl of bundles to be given off are those five which supply the sepals. Alternating with, and above the sepal bun-

dles, is a whorl of five petal bundles. The vascular supply of the ten stamens is in two whorls of five bundles each. Those supplying the stamens which are in the planes of the petals are the first to be given off. Slightly above these, and in the planes of the sepals, the second whorl departs from the cylinder. The numerical symmetry of the bundles of the flowers, and therewith of the gross members of the flowers, ceases at this point. The next whorl of bundles above the stamen bundles is that of the carpel dorsals. The level of these is only slightly above that of the petaled stamen bundles, but they are not in the planes of any of the previous vascular bundles. There were eight carpel dorsal bundles in the flower used for the study of the vascular anatomy; this number is not the same in all flowers. Some distance above the preceding whorl of carpel dorsal bundles, the vascular cylinder breaks up into some fourteen bundles, half of which, alternating (approximately) with the carpel dorsals are placentals, one to each ovule, while the rest enter the style and fade out.

Gaps are formed in the vascular cylinder where the bundles supplying the sepals, most of the petals, and the carpel dorsals are given off. There are none above the stamen bundles and there was none above one of the petal bundles in the flower used for this study. The longitudinal extent of each of the gaps is small, and at no time do they overlap to give the cylinder a dissected appearance.

THE STAMEN.—The first appearance of the stamen is late in July when the buds are still less than one millimeter in length. At this time the anther alone is discernible. During the ensuing two months the filament grows slightly; early in October it begins to elongate rapidly. The filaments of the five stamens opposite the petals are slightly longer than those of the five stamens in the planes of the sepals. The dilated base of each filament is covered with a rather heavy growth of simple, unicellular hairs which are more conspicuous on the dorsal surface than on the ventral.

The anther of the juvenile stamen stands erect. There is a short ridge on the outer side of the lower or proximal end of each lobe (fig. 7). This ridge is to become a part of the margin of the pore. The appendages, of which each anther bears two, are attached to the bases of the lobes, near the lower ends of the ridges. As the filament elongates (October to December) it becomes bent inward at the summit until at maturity the original ventral surface of the anther is on the outside and is flush with the filament. Thus the filament of the mature stamen enters the upper end of the anther and the distal part of the stamen bundle, descending within the anther, is parallel with the proximal part ascending the filament. Meanwhile, the appendages have grown so as to extend horizontally outward from the upper ends of the anthers.

The four microsporangia of each anther are differentiated in September. Each microsporangium consists of a body of pollen mother cells covered by a tapetum of uninucleate cells and two or three layers

of wall cells and an epidermis (in which tannin subsequently accumulates) (fig. 8). The microspore mother cells enter the prophase of reduction division early in October. In the meantime the cells of the tapetum have become binucleate (fig. 9, 14). Reduction division occurred in December in 1939; iron-acetocarmine preparations made at that time revealed the haploid number of chromosomes to be thirteen (fig. 10, 11). Between reduction division and the maturing of the pollen grains, the tapetum disintegrates. The mature pollen grains, found almost immediately after reduction division, are binucleate and are in tetrads (fig. 14).

Frontal sections in the region of the external ridge, of an anther fixed in January, show a line of cells in the first stage of collapse, extending from the proximal end of each microsporangium almost to the epidermis at the base of the ridge on the side away from the median plane of the anther. In the part of the epidermis beyond the end of this line, the cells are smaller and contain no tannin (fig. 15). Sagittal sections of stamens of the same age reveal the collapsed cells to be in a plate (fig. 16). The plate extends across the two pollen sacs with each lobe; it is separated from the epidermis by one row of cells. As the anther matures the width of the row of collapsed cells increases, until at maturity all the cells between the microsporangia and the epidermis have disintegrated. At approximately the same time the wall between the dorsal and ventral microsporangia of each lobe breaks down.

Coincident with the appearance of collapsed cells in the interior, certain hypodermal cells assume distinctive characters. A cross section of the anther near the pores shows these as a parabola or incomplete ellipse, laterally on both sides and ventrally, but not dorsally, with regard to each lobe of the anther. The cytoplasm of these cells remains relatively dense after the cytoplasm of the adjoining cells has been reduced to a narrow peripheral layer. With the collapse and subsequent disappearance of the cells in the area of the pore, the cytoplasm of these cells becomes restricted to a layer adjacent to the cell wall; the nuclei disintegrate and a secondary wall with simple pit-pairs is deposited (fig. 21). The structure described appears to be a rudimentary endothecium; its function, if any, is to strengthen the outer side of the pore.

Soon after the anther becomes inverted and before the flower has opened, the epidermal cells at the proximal end contract. This causes a slit to form among the cells without tannin at the outer base of the ridge. The width of the opening increases, so as to form a pore, by the curling under of the edges. The pores reach full opening as the flowers open (fig. 20).

EMBRYOGENY.—The epitropous ovules first appear in July at which time they are nothing more

than knobs. In December, when the tapetal cells of the anther have become binucleate, the ovule is found to contain an archesporial cell covered by a single layer of nucellar cells, these being covered in turn by an integument, several cells thick and extending to the end of the nucellus (fig. 23). As in all Ericales that have been studied, the archesporial cell functions as the megaspore mother cell. After the megaspore mother cell appears, it develops no further until the integument has grown beyond the end of the nucellus to form the micropyle. The outer layer of epidermis becomes tanniferous as development proceeds. Two successive divisions of the megaspore mother cell then occur to form a tetrad of spores (fig. 24). The chalazal megaspore is functional; the remaining three disintegrate and eventually disappear. The nucleus of the functional megaspore undergoes the usual three successive divisions which result in the formation of a normal embryo sac (fig. 26). The egg and synergids are rather small. The polar nuclei unite before fertilization. The three antipodals soon disintegrate. At this stage in the development the base of the funiculus begins to become extended across the micropyle to form an obturator. Following fertilization the endosperm nucleus divides twice; each nuclear division is followed by cytokinesis. At the same time the micropyle becomes obliterated by growth of the surrounding cells. The second and third cells of the row of four which form after the division of the endosperm nucleus divide in all planes to form the endosperm. The chalazal cell of the four divides longitudinally to form two cells (fig. 28). These later unite into one (fig. 29), and eventually this cell becomes the chalazal haustorium. The course of development in the micropylar cell of the four endosperm cells was not adequately determined. It gives rise to the micropylar haustorium, and there is evidence of a degeneration and destruction of the nearest cells of the endosperm proper under the influence of this structure. It was impossible to distinguish cells or nuclei in the haustoria; in each case they were vacuolated masses of cytoplasm (fig. 31, 32).

The zygote undergoes no divisions until after the endosperm has become many celled. Early in February it elongates to form a tube in which the nucleus is located at the end toward the chalaza (fig. 29). A series of transverse divisions forms a multicellular uniseriate suspensor. The course of the suspensor in the haustorium can be traced, although no cell walls or nuclei can be distinguished (fig. 30, 31). Eventually the terminal cell divides obliquely; continued divisions build up a globular embryo. After the globular embryo develops, the suspensor is absorbed so that the embryo has no contact with the micropylar haustorium (fig. 32).

The stony layer surrounding each seed begins to develop in February. As it becomes thicker and

harder it creates difficulty in sectioning the seed and determining its structure. In June it was found that the embryo had become a cylinder nearly as long as the endosperm, divided to somewhat less than half its length into two cotyledons. The plane of division may either be anticlinal or periclinal to the median plane of the flower. The radicle is bent toward the axis of the fruit. It has grown forward so as to point not toward the micropylar haustorium but past it, on the side toward the summit of the fruit. Both haustoria by this time are much compressed and stain darkly, as if moribund. The obturator has developed so as to form an external cap over the micropylar end of the seed. It is perhaps to be interpreted as a reduced placenta. Such is apparently the mature structure of the seed; seeds collected late in July show no further development.

DISCUSSION.—The features of the structure of *Arctostaphylos* as set forth in this paper agree in all essentials with those given by Samuelsson (1913) and Schnarf (1931) for the embryogeny and with those set forth by Matthews and Knox (1926) for the structure of the stamen.

It is hoped that the data presented will be found useful in the study of the evolution of the Arbutoidae and of their place in the phylogeny of the Ericales, when other members of the group have been examined.

SUMMARY

Arctostaphylos viscida is a shrub common in the chaparral of northern California.

The course of the vascular bundles in the receptacle is described.

The young stamen is erect and bears two appendages at the base. As the stamen matures the filament bends. Thus, the apparently distal end of the mature stamen is really the proximal end. Each lobe of the young anther consists of an epidermis (in which tannin develops), a hypodermal layer (in which a scant rudimentary endothecium develops at the morphologically proximal end), one or two additional layers of wall cells, a tapetum which has a binucleate stage, and pollen mother cells. The haploid number of chromosomes is thirteen. The mature pollen grains are in tetrads. Early in the ontogeny of the stamen, a plate of collapsed cells develops in each lobe of the anther between the pollen sacs and the morphologically proximal end where the pores are to form. By the time the pores open, the area of collapsed cells has increased, so that all the cells between the individual microsporangia and all the cells between the microsporangia and the epidermis are included. Contraction of the epidermal cells in this region causes the pores to open.

The ovules are epitropous. In each a single integument consisting of several layers of cells covers the nucellus. The latter is of one layer of cells. The archesporial cell functions as the megaspore mother cell. The embryo sac is of the normal type. A chalazal and a micropylar haustorium are produced. The embryo is borne on a suspensor.

The plane which divides the embryo into its two cotyledons may be either anticlinal or periclinal in relation to the median plane of the flower.

The mature seed is surrounded by a thick layer composed of stone cells.

A DEVELOPMENTAL STUDY OF THREE SAPROPHYTIC CHYTRIDS.

III. SEPTOCHYTRIUM VARIABILE BERDAN¹

Helen Berenice Berdan

THE DISCOVERY, isolation from a single spore germinated on agar, and the culture of this chytrid have been described in a preliminary report. The generic and specific analyses were also given at that time (Berdan, 1939). Although no essentially different features have been observed since then, cultures of the fungus have been grown in cellophane and lens paper. On cellophane, early stages of zoospore germination and thallus formation showed so clearly that it was considered desirable to add these details, as well as others concerning the later life history, to the previous record.

THE ZOOSPORE AND THALLUS DEVELOPMENT.—The living zoospore (fig. 1, 2) is hyaline, spherical to oval in shape, 4–6 μ in diameter, and with a single posterior flagellum 30–40 μ in length. Normally one highly refractive globule 0.7–3.0 μ (usually about 2 μ) is present in the lightly granular and more or less vacuolated cytoplasm. A small, very shiny granule is situated at the insertion of the flagellum. The method of swimming is typical of most chytrids and the active period varies from a few minutes to several hours, depending upon conditions. The zoospores may undergo the amoeboid, creeping, rolling and jerking movements described many times for the spores of various chytrids. From the sporangia of one heavily infected piece of substratum hundreds of thousands of zoospores emerge. Large, single sporangia have been estimated to discharge from 25,000 to 75,000 spores. Consequently, many variations and irregularities are observed among them, although the percentage of such malformations cannot be computed for comparison with other chytrids. Often, actively swimming spores lack refractive globules, while others, apparently perfectly formed except for a flagellum, are not able to swim at all. Because it is impossible to concentrate attention for a long period on any one spore among the seething numbers milling about on a slide, it has not been ascertained that non-motile spores remain amoeboid and capable of producing infection, as Zopf (1884) has claimed for *Amoebochytrium rhizidioides*. Frequently, spores may contain several globules or bear several flagella. When strong light falls upon the sporangia, immature ones may shed partially developed spores. Then imperfectly-shaped doubled and tripled spores are found and many contain a large, single vacuole causing the spore to appear as an empty ring to which the flagellum is attached. The refractive globule should be measured only from spores of mature sporangia whose discharge has been normal, as otherwise the variability exceeds the normal range. Two or three flagella may be given off from a single point in the spore, the flagellum may be unusually short,

and the loops mentioned for *Cladochytrium hyalinum* (Berdan, 1941a) and *Catenochytridium carolinianum* (Berdan, 1941b) are just as common in this genus (fig. 3). The nucleus appears as a dense area in the cytoplasm. Large spores discharged under unusual conditions may have two or more nuclei present.

Germination of the zoospore is essentially similar to that described for *Entophlyctis* (Karling, 1931a), *Endochytrium* (Karling, 1937a; Hillegas, 1940), etc., of the Rhizidiaceae, and *Cladochytrium replicatum* (Karling, 1931b, 1935) and *C. hyalinum* (Berdan, 1941a) of the *Cladochytriaceae*, but numerous variations may occur. Many zoospores swell and degenerate after coming to rest. The germinating ones usually develop a solitary germ tube, although several may be produced. The tube penetrates into the substratum, where it branches and soon produces the rudimentary rhizomycelium which acts as the absorbing system and upon which the sporangia and swellings typical of the genus are formed. Subsequently, there appears on the germ tube a fusiform swelling which normally becomes the incipient, primary zoosporangium. As this enlarges it occupies a considerable length of the germ tube whose branches become variously oriented upon it and function as rhizoids or branches of rhizomycelium. New branches may develop near the initial swelling and, as it grows, become included as part of the attached rhizoidal system. The empty zoospore case and the germ tube, which varies greatly in length, may soon collapse or be broken off from the developing thallus or may remain adherent well past maturity of the sporangium (fig. 25). After the establishment of the primary sporangial fundament, other swellings arise on the rhizomycelium, some of which are transformed into zoosporangia or resting spores, while many remain unaltered and are emptied of their contents as the thallus matures. The thalli are predominantly polycentric, but under certain as yet unknown conditions many monocentric thalli may be produced.

So many variations occur in the development of this chytrid that it is very difficult to describe any one type as definitely representing the normal. Consequently, a number of specific cases will be recounted from cultures on both cellophane and leaves grown under conditions described previously (Berdan, 1941a).

On cellophane, it is evident that a short, rather blunt germ tube is first developed (fig. 4, 11) and soon begins to branch. Apparently, this occurs whether or not the tube penetrates the substratum, although figure 9 illustrates a spore, lying in water above cellophane, from which three long, smooth and unbranched germ tubes have developed. Next appears the first swelling, which may be either the

¹ Received for publication December 9, 1941.

Contribution from the Botanical Laboratory of Columbia University, under the direction of Professor J. S. Karling.

incipient zoosporangium or a center about which growth is disposed. Figure 6 represents a germinating spore eighteen hours after inoculation of cellophane in a hanging drop. Around it lay many slightly swollen ($7\ \mu$) spores and a number with very short germ tubes. Most spores, however, bore tubes about $40\ \mu$ long and $0.2\ \mu$ wide, while a few measured $100\ \mu$ and had very long branches. Evidently, the rate of germination varies. The spore figured was kept under observation for several days. In figure 6 one incipient swelling is apparent on the germ tube. A day later (fig. 7) a second and larger swelling has arisen between this primary one and the first branches of the rhizomycelium, while further growth and new branches have been produced. The cytoplasm in the spore appears vacuolate at this stage and the globule of refringent material seems to be breaking up into smaller particles which are passing along the germ tube and into the swelling. On the third day, the primary swelling is seen to be greatly enlarged, and the wall is definitely double-contoured. The secondary and intercalary swelling, however, shows no further growth (fig. 8). Each swelling contains a single, large globule and the refringent material in the spore exhibits Brownian movement. On the fourth day, bacterial contamination obscured the observation of any further development.

Figure 13 pictures a young and more poorly developed thallus, whose one swelling, nevertheless, contains a large globule of refringent material while the spore is absolutely empty. There seems to be no correlation between the extent of the young rhizomycelium and the passage of refringent material from the spore.

In many instances, the rhizoidal tips penetrate the cellophane in from eighteen to thirty-six hours' time. Figure 20, however, illustrates a spore with a germ tube $160\ \mu$ long with a primary branch $100\ \mu$ in length and several secondary ones. There is a single swelling containing several refringent globules on the germ tube. Nevertheless, this rather highly developed thallus has secured no entry into the cellophane. Adjacent to it is the spore shown in figure 19, where the germ tube, which is but $32\ \mu$ long, has its tip firmly imbedded, and several swellings are developing upon it.

The extramatrixal zoospore may develop one to several extramatrixal germ tubes, and even a portion of the primary sporangium may be found outside the substratum (fig. 15a, 15b). In these figures the infecting germ tube is so short that the sporangial fundament seems to be adherent to the zoospore. Partially imbedded in the cellophane, it has caused this material to crack radially around it, and apparently some dissolution of the substratum has occurred. This is a very common appearance on cellophane and helps to locate the young thalli. In figures 5, 15a and 15b the initial swelling seems to have occurred along a branching portion of the germ tube so that a number of rhizoids have become laterally oriented upon it. A discussion of such rhizoid arrangement has been given in some detail by Karling

(1931a) for *Entophlyctis* and need not be described here. In figure 15a the swelling is still fairly fusoid and contains only a few globules, but in figure 15b, the sporangium is becoming irregularly shaped and the cytoplasm is filling with refringent material. Obviously, variation in shape is often determined at an early age. In both these figures many branches of the rhizomycelium could not be drawn, since they were imbedded in the cellophane above and below the sporangial fundament and the actual tips were obscured.

In figure 12a, most of the rhizoidal system between the spore and the branch bearing the sporangial rudiment, although swollen and constricted, is extramatrixal. In figures 12b and 14, the very long, narrow, smooth filaments are extramatrixal, while the intramatrixal ones are swollen, nodular, and constricted, which is very characteristic of *Septochytrium*. Many globules of refringent material are collecting in the primary swellings and travelling forward along the rhizomycelium. In figure 19 is represented a complete young thallus in which the cytoplasm is rather vacuolate, but glistening and shiny and containing a few refractive globules. The swollen and constricted character of the rhizomycelium is also clearly shown in this figure. Figure 21 illustrates a more advanced thallus, with a well-developed incipient sporangium. The rhizomycelium is imbedded in the cellophane and is fairly coarse ($2\ \mu$), while refringent material is accumulating in the sporangial rudiment.

In figure 10 is shown a portion of a young polycentric thallus after three days' growth in a hanging drop. The zoospore case is empty and beginning to collapse. Two rudimentary sporangia are forming and on the rhizomycelium, which measures $300\ \mu$ in length, are several fusiform swellings characteristic of this genus. Figures 22 and 23 show two thalli after three and seven days' growth, respectively. In the former, although it is still monocentric, the typical septations, constrictions, and swellings are becoming apparent. In the latter, the primary sporangium measures $26\ \mu$, the chief strand of rhizomycelium is $4.5\ \mu$ wide and several other branches are $4\ \mu$ in width. At least four more sporangia are in process of development and many constrictions, septations, etc., are indicated, although the full extent of the rhizomycelium is not shown because many fine branches are obscured by the cellophane in which they are imbedded and by their intermingling with branches of neighboring thalli.

Sometimes, during this period, a single sporangium enlarges and matures (fig. 25) so that a thallus of a simple monocentric rhizidiaceous type as in *Endochytrium* is produced. Other thalli become extensively polycentric, bearing branches with three and four sporangia in sequence. In these, the primary swelling frequently does not become a sporangium, but loses its contents, and to all appearances, remains functionless. Apparently, it has acted only as a temporary store-house or center from which protoplasm has migrated to new regions. These ini-

Fig. 1-16.—Fig. 1, 2. Zoospores.—Fig. 3. Zoospore showing loop on flagellum.—Fig. 4. Young germination stage in water above cellophane.—Fig. 5. Young stage of germination, showing primary sporangial fundament.—Fig. 6-8. Young

tial swellings may become very large and upon emptying turn brown and collapse.

In figure 26 is represented part of a mature polycentric thallus, in which the sporangia have been delimited from the rhizomycelium by the true cross walls and are both terminal and intercalary in position.

Infection of bits of sterile corn leaf in hanging drops gives similar germination stages, one of which is represented in figure 24. The germ tubes of zoospores frequently exhibit a form of tropism during their early development. Figure 17 illustrates a large, extramatrical sporangium with its rhizoids in cellophane, and which has shed its spores. Without exception, upon germination, the tubes have become oriented toward the substratum, and many have entered it. Two days later, only one tube was continuing to grow, even though the primary incipient swelling had been developed previously upon most of the others. This one (fig. 18) eventually developed a mature thallus with a sporangium.

When this chytrid was first discovered and grown in leaves of grass (July, 1938) and later in wheat leaves, the zoospores tended to accumulate near the stomata and the cut ends of the leaves. This is not uncommon and has been recorded for other chytrids (Cox, 1939; Haskins, 1940, etc.). From the spore, a fine germ tube then passed through the stomatal opening or penetrated the wall of the guard cell and developed the primary sporangial fundament in the leaf cells directly beneath. On the cut surfaces, the swellings developed near the point where the tubes entered the leaf. As a result, large groups of sporangia were found clustered about the stomata and along the ends of the leaf. The spore and the fine extramatrical portion of the germ tube usually shrivel up or are torn away so that these primary sporangia often appear to be terminal on the rhizomycelium. In tough leaves of certain varieties of corn, the spores become caught on the sharp spiky cells along the edge or on spiny epidermal hairs. Under such conditions, a great part of the rhizoidal system develops extramatrically, but the primary sporangial rudiment is always formed in the leaf cell (fig. 16). When such sporangia become very large, they fill the host cell and frequently distend it. The thalli might be either monocentric or polycentric under these circumstances.

Figure 27 shows a group of young thalli developing from spores near the stoma of a wheat leaf. It was drawn two days after the spores had been discharged into a new culture. Here, the nearly empty spore cases measure about $4.5\ \mu$, while the sporangial fundaments are about $8\ \mu$. The cytoplasm is hyaline

but glistening with a whitish gleam. A few strands of cytoplasm and a small portion of the refractive globule are still left in some spores. Vacuoles are not pronounced in the cytoplasm of the rhizoids which have an average length of about $100\ \mu$ and are branching.

A group of young thalli in the same leaf, drawn a day later (fig. 28) has greatly enlarged swellings and much heavier rhizoids. Several spore cases are still adherent. These swellings become sporangia, are cut off basally from the rhizoids by cross walls and at maturity develop broad necks which extrude through the stomata to open by an operculum and discharge their spores.

Although the thalli are commonly polyrhizoidal, they may often be monorhizoidal. The rhizoids or branches of rhizomycelium are oriented basally and laterally upon the sporangia as a rule (fig. 27-30), but when the sporangia are very large and centrally situated may often be so placed as to give a radiating appearance (Berdan, 1939, fig. 2). There are from one to twelve points of insertion, terminally placed sporangia often having but one, and intercalated sporangia but two, although here again a great variation exists. The extent of distribution and the size of the rhizomycelium (or rhizoids) is most unusual and comparable to that described for *Endochytrium operculatum* (Karling, 1937a) and *Rhizophlyctis Petersenii* (Sparrow, 1937; Haskins, 1940). The diameter of the rhizoids at the point of insertion on the sporangium ranges from 0.4 to $12.0\ \mu$, while the extent covers from $20\ \mu$ to $1\ \text{cm}$. Rhizoids extending into leaf tissue from sporangia formed near a cut edge are commonly very thick ($8-12\ \mu$) and remain so for long distances before beginning to taper. Those running parallel to and near by the midrib of a leaf tend to be straight and tubular and to follow in the long, narrow cells as a stout central axis with numerous branches. For example, one rhizoid near the mid-rib of a tough corn leaf extended $750\ \mu$ at a diameter of $8\ \mu$, giving off branches of varying width all along that length. Another filled the lumen of a fibre of lens paper for a length of $600\ \mu$.

At maturity, the rhizoids seem almost empty, containing but a few dark-colored globules and granules. The walls tend to become a light brown color. Earlier (fig. 29, 30), the hyaline cytoplasm is glistening, fairly homogeneous and contains small globules. The constrictions, partial septations, etc., that seem to be present in nearly all rhizoids during some stage of their development (fig. 22, 23, 26, 30, 41, 51) are so inconstant that it is almost impossible to give a representative description of them. True septa delimit the zoosporangia and resting spores from the rhizo-

developmental stages of the thallus during four days' time in a hanging drop.—Fig. 9. Spore germinating in water above cellophane to produce three long, smooth, unbranched germ tubes.—Fig. 10. Young polycentric thallus beginning to develop.—Fig. 11. Germinating spore showing branched germ tube 18 hours after inoculation of cellophane in a hanging drop culture.—Fig. 12a, 12b. Primary sporangium being developed. Note that the zoospore case and smooth narrow germ tube are extramatrical and adherent at some distance from the sporangial fundament.—Fig. 13. Young stage of germination with empty zoospore case. Refracting material is collected in a single globule in the sporangial fundament.—Fig. 14. Similar to 12a, 12b.—Fig. 15a, 15b. Young sporangia being developed in cellophane. The cellophane is cracking radially about the thallus.—Fig. 16. A zoospore germinating on a spiny cell at the margin of a wheat leaf.

Fig. 17-26.—Fig. 17. Spores from the empty sporangium beginning to germinate. The germ tubes exhibit tropic movement in the direction of the substratum, cellophane.—Fig. 18. The single spore from figure 17 which continued to develop. Eventually a thallus with a sporangium matured from this.—Fig. 19. Young thallus in cellophane.—Fig. 20.

mycelium at maturity and often appear convex (fig. 41, 51). Whether or not septa are present in other positions along the rhizomycelium and rhizoids is still somewhat questionable, but bands or trabeculae of some opaque material extend partially or entirely across the width of the filaments in many places (fig. 31, 32, 41, 50, 51). They are not infrequent at the point of branching and may be transformed remnants of cytoplasm and refringent material rather than actual septa. In some rhizoids or even in whole thalli, very few constrictions or swellings occur, while in others they are numerous and arranged either in series or at intervals of about $10\ \mu$. Even in a single spore strain there is such a range of variation that it becomes difficult to distinguish that which is typical.

The swellings of the rhizomycelium are comparable to the spindle organs, "Sammelzellen," etc., of other genera of the Cladochytriaceae, except that there is a much wider range in size and shape. They are non-septate, continuous with the rhizomycelium and formed singly or in conjoining series. In the latter case, they seem to be separated by opaque bands similar to those elsewhere throughout the rhizomycelium, and rhizoids may often originate upon them. The swellings are commonly spherical, ovoid or fusoid in shape, but polyhedral, turbinate or irregularly shaped ones are not uncommon. In size, they are $2\text{--}100\ \mu \times 2\text{--}200\ \mu$ (usually $15\ \mu \times 20\ \mu$). The extremely large turbinate to polyhedral or irregular organs result chiefly from primary swellings which lose their contents before zoospores can be formed. In one such instance a large ($50\ \mu \times 100\ \mu$), thin-walled organ gave off twelve branches of rhizomycelium. These extended over $1,500\ \mu$ without taking into account the finer rhizoidal branches. Large ($40\text{--}75\ \mu \times 50\text{--}125\ \mu$) primary sporangia, which were spherical, ovoid or pyriform in shape, formed on five of them. Other secondary and tertiary sporangia as well as many ordinary swellings were also produced. One branch of the rhizomycelium bore four sporangia while another produced none at all. In a second case, two branches of rhizomycelium given off from such a swelling produced eleven sporangia. It seems to the writer that extremes of polycentricity may result when the original swelling does not become a zoosporangium, but the contents migrate from it after it has reached large proportions. At first, the swellings contain clear, shiny cytoplasm and refringent globules. Later, they either are empty or retain small amounts of dark material in more or less globular condition. Occasionally, they seem to have divided into two cells, one of which forms a zoosporangium or resting spore while the other remains attached as a sort of apophysis.

The development of the zoosporangium is essentially like that recounted many times previously for various chytrids and particularly as outlined for *Endochytrium operculatum* by Hillegas (1940) so it need not be described again. The alveolar stage described for *Catenochytridium* (Berdan, 1941b) is also found in many of these sporangia and seems to persist for a longer time period. This condition has been described and figured for *Nepbrochytrium stellatum* (Couch, 1938) as a normal part of the internal changes during sporangium development. Here Couch illustrates the continued presence of such vacuoles during all the stages of coalescence of the refringent material. This same condition has been noted frequently in *Septochytrium*, especially in long, narrow sporangia, but positive evidence has not been secured that normal spores are later discharged from these sporangia. One sporangium under observation required $10\frac{1}{4}$ hours to pass through all the internal changes from the time it was delimited from the rhizoids until all the spores were discharged.

The shapes and sizes of sporangia have been given previously by the writer (1939) and are illustrated here in figure 51. Small sporangia are found which contain but one zoospore. Others are so large that they can be observed in the substratum with the naked eye. In flask-shaped, pyriform, tubular, etc., sporangia some distinction seems necessary between the sporangium proper and the "exit papilla" or "neck" at the tip of which the operculum is formed. Since, at maturity, the whole interior of the sporangium, regardless of its shape, becomes filled with spores, it seems reasonable to consider only the hyaline region directly beneath the operculum as the exit papilla. When lobes and projections of sporangia are not special structures for the exit of zoospores and are not set apart in any way from the remainder of the sporangium, they should not be termed "exit tubes." Nevertheless, every sporangium bears a short, broad, papillate portion which extends to the exterior before the operculum opens. In leaves, it may crowd out through a stoma. In cellophane, the imbedded part often has a brown wall while the extramatrix portion remains much paler in color. When the rudiment forms just below the surface of the substratum which is afterward ruptured by the large and swelling sporangium, the latter may seem to become completely extramatrix in situation, and many rhizoids extend out into the surrounding water.

The region in which the operculum will form is marked out as a hyaline area just below the wall of the exit papilla. Under high magnification, the wall of the sporangium seems to be made up of more than

Extension germ tubes, one branch bearing a swelling, lying in water above cellophane.—Fig. 21. Similar to 19, but more advanced.—Fig. 22. Similar to 21. The thallus is becoming extended and typical swellings and constrictions are developing on the rhizomycelium.—Fig. 23. A stage of development later than that in figure 22. The thallus is polycentric and rhizomycelium coarse, swollen and constricted with trabeculae or false septa extending across its width.—Fig. 24. Young stage of thallus from a zoospore germinated on a corn leaf in a hanging drop.—Fig. 25. A monocentric thallus. The sporangium is maturing but the zoospore case is still adherent.—Fig. 26. Polycentric thallus producing five sporangia. Two have shed their spores.

Fig. 27-50.—Fig. 27. Group of young thalli from spores whose germ tubes have entered through a stoma of wheat leaf.—Fig. 28. A stage two days later and from the same leaf as in figure 27. Note increase in size of sporangial funda-

one layer. The outer one apparently thickens to form the "cap" (operculum) while the inner one seems to swell or bulge inwardly (fig. 35, 37, 38, 39). Karling (1937a) has described this region in *Endochytrium operculatum* as being filled with a viscid hyaline fluid and such may be the case here, although figures 33, 37, 38, 39 seem to indicate some connection with the wall. Plasmolysis of this region does not cause this area to shrink back with the plasma membrane. Figures 36 and 40 illustrate two puzzling cases where the outer layer of the wall appears to have broken off or to be abruptly truncated, while the inner layer and sporangial contents protrude through the opening.

In figure 34 is shown the sequel to figure 33. The operculum has been pushed off but is still attached to the sporangium by a very fine membrane. The first sign that the operculum is about to be forced off is the appearance of a thin ring in the outer layer of the wall just below the thickened "cap." Sometimes the lid is actually separated from the rest of the sporangium by this thin area as is indicated by two fine lines ringing the "neck" of the sporangium. It may remain hinged to the sporangium but usually is carried upward by the emerging spores. Although many sporangia with branches or extended arms have been seen (fig. 51), especially in old tough corn leaves and cellophane, only once has a sporangium produced two opercula. The orifice is circular, $1-16\ \mu$, or oval, $4-6\ \mu \times 6-10\ \mu$. The first material to emerge after dehiscence is clear and possibly represents the hyaline content present in the region just beneath the operculum. When the operculum is attached and lying below the exuding spores, where it acts like a rounded gang-plank, the spores slide down over it two or three abreast. Their long flagella trail behind as fine dark lines and make channels into which the succeeding spores must crowd as they escape. The effect is of striations on the sporangial wall until careful observation interprets it otherwise. The sporangial wall does, indeed, become brown and wrinkled with age but not until later. Sometimes, the crowding spores are squeezed into hexagonal patterns. Again, some may be very amoeboid or stretched out into long, narrow shapes as they reluctantly make an exit. This happens frequently when sporangia are borne among the meshes of fibers in lens paper. Then the spores become entangled and exhibit striking amoeboid and elastic movements. From small sporangia the spores are usually extruded all at once in a globular mass which remains quiescent for a few moments. Then the mass loosens up and spores begin to dart out of it. When large numbers (75,000) of spores are discharged from a single sporangium, the first ones form a ball, and later ones are hampered in their exit by its presence and must either push it aside or stream around it to form irregular masses nearby which may cover areas

of $100\ \mu$. Nevertheless, these, too, remain quiet before swimming away. Laggards have great difficulty in escaping, since the opening is choked by the preceding spores, so that germination "in situ" is common. Many of these trapped zoospores go into a resting condition and upward of 75 small resting spores may be counted in an old sporangium. Then it is not possible to ascertain the method of germination of the zoospore. Hillegas (1940) reports a similar phenomenon for *Endochytrium operculatum* and fails to find evidence of rhizoids but considers that the zoospores have enlarged directly. The time required for exit of the zoospores naturally depends upon the size of the sporangium. The spores are usually swimming actively within three minutes of their discharge.

RESTING SPORE DEVELOPMENT AND GERMINATION.—Resting spores are commonly developed when conditions are unfavorable for zoospore production or discharge. They may form from any of the swellings on the rhizomycelium from which zoosporangia are normally produced and in any of the positions described previously for the latter structures.

The internal changes which take place during the formation of the resting spore of *Septochytrium* are essentially similar to those described and figured many times previously for various chytrids and are, therefore, not recounted again in detail nor illustrated. The first sign that a resting spore is about to develop is the increase of the refractive material in a swollen sporangial rudiment, unaccompanied by further enlargement of the cell or signs of zoospore formation. As the increase continues, the refringent material fuses into large, irregular globules. Then the wall begins to thicken and to turn brown. Finally, one large globule of brownish, oily substance is formed, while around it in the peripheral cytoplasm, a layer of small globules (fig. 41) which may be packed closely into a surface, hexagonal pattern, is produced. At maturity the wall is layered (fig. 41, 45, 50), $1.5-4.0\ \mu$ thick, and pale amber to dark brown in color. The outer layer is not always of equal thickness throughout and although generally smooth, may be somewhat roughened or uneven. Adjacent branches of rhizomycelium often tend to develop brown and thickened walls, also.

The resting spores are spherical, ovoid, pyriform, flask-shaped or much elongated in shape and $4-60\ \mu \times 4-65\ \mu$ in size (fig. 52). Up to the present no evidence of sexuality has been seen in connection with the production of resting spores.

At germination, the resting spore functions as a prosporangium. The preliminary changes in the content prior to germination are primarily the same as those described many times previously for various chytrids (Berdan, 1941a). However, the resultant zoosporangia may be in direct contact with the resting spore through the pore in its wall (fig. 42, 46), or they may be formed at the end of a tube produced

ments and width of rhizoids.—Fig. 29, 30. Portions of young thalli. The primary sporangial fundament has become thick-walled while constrictions and swellings are forming in the rhizomycelium.—Fig. 31, 32. Portions of the rhizomycelium showing opaque bands which pass entirely or partly across its width.—Fig. 33-40. Views of operculum in various stages.—Fig. 41. A mature resting spore.—Fig. 42-50. Stages and variations in resting spore germination.

Fig. 51-52.—Fig. 51. Outline drawings to indicate range in size and variation of the zoosporangia.—Fig. 52. Outline drawings illustrating various shapes of resting spores. Note position of the large globule.

by the germinating spore (fig. 42-45 and 47-50). As the tube gradually elongates, the protoplast of the spore empties into it and eventually concentrates in the tip to form an operculate zoosporangium which is delimited by a cross wall. The first type of zoosporangium mentioned above is usually spherical, pyriform or ovate while the second variety is oval, rounded pyriform, clavate, obclavate, etc. In size they are proportionate to the resting spore from which they are derived. The tube may be wide and sac-like (fig. 45) to very long and narrow (fig. 43) when it may have twists, coils (fig. 44) or branches (fig. 49). According to a preliminary paper, it is $7-26 \mu \times 10-450 \mu$ in size. Since then, using cellophane as a substratum, tubes as narrow as 2μ and as long as 700μ have been found.

The resting spores were first seen to germinate in the laboratory at Columbia University after an air-mail trip in stoppered test-tubes from London, Canada. Since then, germination has occurred a number of times but never again in such quantity.

DISCUSSION.—This genus has been placed in the family Cladochytriaceae, since it is predominantly polycentric and possesses a rhizomycelium bearing numerous rhizoids and terminal and intercalary swellings which may at maturity be transformed into zoosporangia or resting spores. As it stands at present, there is but one valid operculate genus, *Nowakowskiella*, in this family. According to the description as given by Schroeter (1897), the zoosporangia are usually apophysate and proliferating one to several times. While sporangia of *Septochytrium* occasionally arise in such a manner as to appear apophysate, no proliferation has been seen up to date. There are but two established species of *Nowakowskiella*, and one other whose validity is questionable. *N. elegans*, the type species, has been grown by the writer a number of times and has a much more delicate and tenuous rhizomycelium than *Septochytrium*. The measurements of zoosporangia as given by Nowakowski (1876), Schroeter (1897), Matthews (1928), and Sparrow (1933) are also much smaller than in the present species, while the presence of resting spores has not been ascertained with certainty. *N. ramosa* (Butler, 1907) has a unique type of resting spore which has been discussed thoroughly in connection with *Cladochytrium hyalinum* (Berdan, 1941a) and resembles that of *Septochytrium* in no way. Since *N. endogena* has been figured by Constantineanu (1901) as monocentric and lacking intercalary swellings, it cannot justifiably be included in the genus as it is described at present. Nevertheless, there is a slight possibility that our fungus is a new and hitherto undescribed species of *Nowakowskiella*, although it disagrees with the current diagnosis of that genus.

A new genus, *Megachytrium*, was established by Sparrow (1933) for a chytrid which has occasionally apophysate sporangia, a thick and sometimes septate mycelium and terminal or intercalary swellings. Yet it lacks rhizoids and the swellings are cut off from the rhizomycelium by cross walls, which

seems to separate it effectively from *Septochytrium*. *Endochytrium ramosum* as described and figured by Sparrow (1933) is a polycentric form with a profusely branched rhizomycelium bearing rhizoids and operculate zoosporangia but lacking swellings. No formation of resting spores has been observed for this species. The monocentric species, *E. operculatum*, resembles monocentric thalli of *Septochytrium* in the variation of shape, size, etc., of sporangia, resting spores, and type of development of the thallus. Hillegas (1940) has reported an instance where two resting spores were developed on the same thallus of *E. operculatum* and suggests that this may indicate a trend toward polycentricity. *Septochytrium* is often monocentric. Perhaps these combined data may suggest some evolutionary connection between the genus *Endochytrium* of the Rhizidiaceae and the operculate genera of the *Cladochytriaceae*. Certainly the limits of the two families do not seem to be quite so sharply defined as previous diagnosis might lead us to believe, and in some genera the cause of duplication of polycentricity of the thallus may be more environmental than inherent.

In consideration of the findings of Karling (1937b) and Hillegas (1940) for *Cladochytrium replicatum* and *Endochytrium operculatum*, respectively, a cytological study of nuclear behavior in *Septochytrium variable*, where the percentage of monocentric thalli seems fairly high, might be of considerable interest and illumination as regards transition from the rhizidiaceous form of thallus to the polycentric type found in the *Cladochytriaceae*.

SUMMARY

The details of the life history, with particular emphasis on germination stages in cellophane, are described for this chytrid, recently reported and diagnosed as a new genus.

It is extremely variable, so the isolation of a strain from a single spore was deemed necessary and the description is taken from this strain.

The genus is placed in the family Cladochytriaceae because of its predominantly polycentric rhizomycelium with numerous swellings from which the zoosporangia and resting spores are developed.

The sporangia are operculate but rarely apophysate. Consequently the relation to *Nowakowskiella* and *Megachytrium* is discussed.

The range in variation of size and shape of sporangia and resting spores and in development of the thallus is very wide.

No evidence of sexuality is found in the development of the resting spore.

At germination, the resting spore functions as a prosperangium. Zoosporangia may be formed in direct connection with the spore by means of a pore in the wall, or at the end of a tube produced from the resting spore. The tube may be saccate and broad, or extremely long and narrow, straight, coiled, twisted or branched.

Polycentric thalli are unusually extensive.

Monocentric thalli are often formed. In size and general characters these are similar to *Endochytrium operculatum* Karling but the rhizoids do not conform accurately to the description in that genus.

DISTRIBUTION OF STRUCTURAL HYBRIDS IN *PAEONIA CALIFORNICA*¹

James L. Walters

THE OCCURRENCE of structural hybridity in the chromosomes of *Paeonia* subg. *Onaepia*, owing to extensive reciprocal translocation and inversion, was first reported by Stebbins and Ellerton (1939). This subgenus is composed of the two American species, *P. californica* and *P. Brownii*, the former inhabiting coastal southern California and the latter a portion of montane western North America (Stebbins, 1938a). Stebbins and Ellerton thoroughly analyzed the ring configurations found in collections of *P. Brownii* from two localities and of *P. californica* from one. The present paper will deal with the broad aspects of the distribution of structural hybrid features of *P. californica* throughout its range. A more complete analysis of structural hybridity in the chromosomes of both species will be furnished in a later publication.

MATERIAL AND METHODS.—Material of *P. californica* was collected in various parts of its range, extending from the northernmost known station (near King City, Monterey County) to points along the border between San Diego County and Lower Cali-

fornia. The latter is not far from the southernmost known locality. The collections in most regions also include the farthest inland extensions of the range. The accompanying map (fig. 10) shows the distribution of the collections throughout the range of the species. Flower buds were fixed in 3:1 absolute alcohol-glacial acetic acid overnight, then washed and stored in 70 per cent alcohol. Anthers were softened by placing in iron aceto-carmin for fifteen minutes in the paraffin oven (54°C.) and then smeared in the usual manner. The studies of meiotic configurations were made using a 90× apochromatic objective with 15× compensating oculars. The photomicrographs (fig. 1-6) were taken with the same optical equipment, and a Leitz Makam camera.

TYPES OF STRUCTURAL HYBRIDS.—The chromosome number in *P. californica*, as in most other species of the genus, is $n=5$. All five chromosome pairs have been identified in somatic tissue and given letter designations (Stebbins, 1938b). In meiosis, the three pairs with median centromeres cannot be distinguished from one another, and are labelled *M*, but the submedian (*D*) and the subterminal (*E*) pair are readily recognized in most cells (fig. 1-4). It should be emphasized that the recognition of these chromo-

¹ Received for publication December 9, 1941.

The writer wishes to express his gratitude to Dr. G. L. Stebbins, Jr., who suggested the problem and has given much advice and assistance in carrying it forward.

some types does not necessarily imply strict homology between similarly lettered chromosomes in the various species, or even between "homologous" chromosomes in the same plant of *P. californica*, as pointed out by Stebbins and Ellerton (1939). Since extensive reciprocal translocation has taken place in this species (and the related *P. Brownii*), it is clear that homology exists only in terms of parts of chromosomes. In certain plants it has been possible to show that unequal translocation has altered the relative lengths of chromosome arms so that in these plants the type of a given chromosome may be uncertain (Stebbins and Ellerton, 1939, fig. 2). Such changes in homology have also been studied by Sax (1931) in *Rhoeo discolor*, and he has pointed out that it is not possible to match all of the twelve chromosomes of this species into homologous pairs.

The chromosome configurations now known in *P. californica* include all combinations of pairs and rings possible with ten chromosomes. These configurations are as follows: 5_{II} (fig. 1); $\odot 4^2$; $\odot 6$; $2 \odot 4$ (fig. 2); $\odot 8$ (fig. 3); $\odot 6 + \odot 4$; and $\odot 10$ (fig. 4). The studies of Belling and Blakeslee (1926) and many others have shown that the existence of such rings of chromosomes in meiosis is due to reciprocal translocation between non-homologous chromosomes. This gives rise to chromosomes each of which is homologous with two other chromosomes, one at each end. The process is too well known to require further elaboration here. One reciprocal translocation produces a $\odot 4$. A second translocation produces a second $\odot 4$ if it involves none of the four chromosomes in the first ring; or a $\odot 6$ if any of these four is involved. A third translocation in either a $\odot 6$ or a $2 \odot 4$ plant results in a $\odot 8$ or a $\odot 6 + \odot 4$ type, depending again on the chromosomes involved in the new translocation. A fourth translocation produces the complete $\odot 10$. It should be noted that these are the *minimum* numbers of translocations required to produce each of the rings just described; other translocations (termed "redundant" by Darlington and Gairdner, 1937) may occur, which do not increase the size of the ring.

There are of course more than seven types of configurations with respect to the arrangements of their chromosome segments, owing to the fact that a ring containing a given number of chromosomes may in different plants include different chromosomes. To some extent, these differences can be detected, since two of the pairs may be distinguished from the other three and from each other. Thus, a plant with $\odot 4$ collected at Pozo, San Luis Obispo County, has four *M* chromosomes in the ring; a $\odot 4$ type from west of Pasadena, Los Angeles County, has two *M* chromosomes and the two *E* chromosomes in the ring; one from Sepulveda Canyon, Los Angeles County, has two *M* chromosomes and the two *D* chromosomes in the ring. This represents all the differences that can be detected cytologically in the ring of four. Two of these are shown in the $2 \odot 4$ type from Altadena (fig. 2). Similar differences have been recognized

² The symbol \odot means "ring of."

in the larger rings, and the complete data will be presented in a later paper.

This complete series of structural hybrids parallels the situation known in *Oenothera* subg. *Onagra* (Cleland, 1936, and others), and exceeds in extent any of the other reported cases of naturally occurring structural hybrids (Darlington and Gairdner, 1937, on *Campanula persicifolia*; Sax, 1931, on *Rhoeo discolor*; Hoar, 1931, on *Hypericum punctatum*; Kattermann, 1938, on *Briza media*).

INVERSIONS.—The occurrence of extensive inversion hybridity was mentioned by Stebbins and Ellerton (1939), and only a brief confirmative mention will be made here. Inversions are so extensive as to be ubiquitous; the author has never observed a plant which did not show at least a small percentage of the familiar bridge-fragment configurations in first or second anaphase. These will be reported on more fully in a later publication. A rather striking configuration is shown in figure 6, where a "diagonal" bridge may be seen at second anaphase. In this cell, non-disjunction has taken place at first anaphase, as two *E* chromosomes may be seen in two of the anaphase groups and two *D* chromosomes in the other two. The way in which the bridge is related to the non-disjunction shows clearly that the bridge is a surviving first-anaphase bridge, and not the result of disjunction of a loop chromatid (Darlington, 1937, pp. 265-9). It is also clear that the inversion is in an *M* chromosome. The fragment may be seen adjacent to one of the chromosome groups.

DISTRIBUTION OF THE RING TYPES.—It has been mentioned that the collections reported on here cover a representative part of the entire range of the species, including the northern, southern, and inland limits. The geographic distribution of the structural hybrid types throughout this region shows an interesting feature: there is a tendency for plants occurring near the limits of the range of the species to be more highly heterozygous than those growing near its center of distribution. This tendency is shown on the map (fig. 10), where the different types are shown by symbols. In San Diego County, only the higher heterozygotes are found: $\odot 8$; $\odot 6 + \odot 4$; and $\odot 10$. These types are also known from Riverside County, with the addition of $2 \odot 4$. At the northern extreme, in Monterey County, high heterozygosity is also found, though it is less striking here than at the southern extreme just described. In Monterey County $\odot 8$ is known from two collections, and $\odot 6$ from one. In the intermediate areas, though high heterozygotes are present (the highest being $\odot 8$), the proportion of homozygotes and low heterozygotes is large. This is particularly clear in San Luis Obispo and Santa Barbara Counties; homozygotes will also be noted in Ventura, Los Angeles and Orange Counties, where, however, fewer collections have as yet been made.

It is not to be implied from the above description that any one area is always homogeneous as to the ring types it includes. *Paeonia californica* grows, in most areas studied, in clearly defined colonies of

usually not more than a hundred yards in extent, with intervals between colonies ranging from a half mile to many miles. The majority of the collections were made by taking at random ten plants of each colony. In some cases, examination of the ten plants has shown remarkable heterogeneity within the colony. For example, the collection from west of Pasadena, Los Angeles County, shows the following distribution: 1 plant with 5_{II} ; 4 plants with $\odot 4$ (MMEE); 2 plants with $\odot 4$ (MMMM); 2 plants with 2 $\odot 4$ (MMMM + MMEE); and 1 plant with $\odot 6$ (MMMMDD). The collection (8 plants only) from San Juan Hot Springs, Orange County, is interesting in that no single-translocation form ($\odot 4$) was found: included are 4 plants with 5_{II} ; 3 with $\odot 6$; and 1 with 2 $\odot 4$. On the other hand, a colony collected just north of Altadena (about 5 miles from the colony west of Pasadena) is found to be entirely homogeneous, showing 2 $\odot 4$ in all ten plants collected. The heterogeneity of the various colonies will be described more fully in a later publication. The information obtained up to the present time indicates that the maximum variability in any one colony does not exceed two translocations (the difference between 5_{II} and $\odot 6$, for example).

DISCUSSION.—A comparison may be made between the regularities just noted in the distribution of *Paeonia californica* structural hybrids and certain features of the distribution of American races of *Oenothera* subg. *Onagra* (Cleland, 1940). In the latter group, the regularities are perhaps more striking. California is occupied by the *hookeri* alliance, composed chiefly of forms with 7_{II} or small rings. In New Mexico the *irrigua* alliance is found, characterized by rings of intermediate size such as $\odot 6$, or $\odot 6 + \odot 4$, or $\odot 8$. The *Jamesii* of Oklahoma show a similar situation. In the eastern part of the range, practically all races show the complete $\odot 14$. The races of the *Rydbergii-strigosa* assemblage of the northern and eastern Rocky Mountains and the great plains also show complete rings. This completely heterozygous type, then, occupies the major portion of the range of *Onagra* in North America.

This predominance of the complete ring in *Onagra* suggests that this type has a higher survival value than the smaller rings or the structural homozygotes, and Cleland (1940), following Darlington (1929), has advanced a likely explanation of this advantage. Briefly, he views the complete ring as a mechanism

for ensuring maximum heterozygosity (and thus heterosis) under self-pollination, since a single pair of balanced lethals is in this case sufficient to preserve heterozygosity. The pair of lethals reduces fertility by 50 per cent, but "with heterozygosity of all or practically all the chromosomes thus preserved, cross-pollination would no longer be of value, and the increased certainty of seed setting resulting from self-pollination would probably more than make up

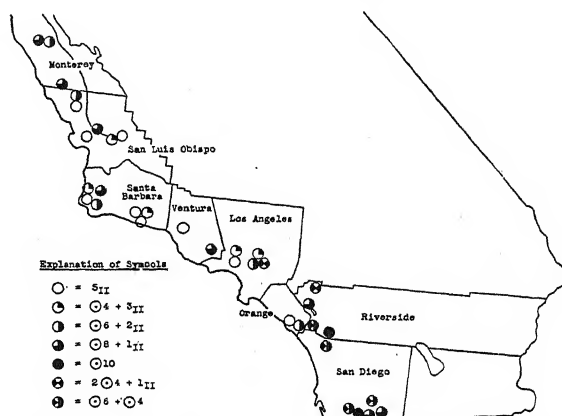

Fig. 10. Map of the southern half of California, showing the counties in which *Paeonia californica* has been collected, and the distribution of the structural hybrid types. Further explanation in the text.

for the sterility due to the lethals" (Cleland, 1940). In *Paeonia californica*, the distribution of the various ring types does not show the clear-cut differences reported by Cleland for *Onagra*, nor does the completely heterozygous type occupy the major portion of its range (as the map shows). Further, no area within the range of *P. californica* is exclusively occupied by the complete ring, in sharp contradistinction to *Onagra*. In the related *P. Brownii*, however, there is some indication that the *Onagra* situation is more closely approached; more complete data must be obtained before any definite statement is possible.

From present evidence, therefore, it does not appear that any one type of configuration in *P. californica* is significantly more abundant than any of the others, and thus it is not possible to say that in this species the complete ring, or any other configuration, has a superior survival value. There are two

Diagrammed in figure 7.—Fig. 3. $\odot 8 + 1_{II}$; late metaphase. The pair is interlocked with the ring; the chromosomes of the ring are alternately distributed. The significance of the interlocking is discussed in the text. Los Alamos, Santa Barbara County. Diagrammed in figure 8.—Fig. 4. $\odot 10$; early metaphase. Failure of chiasma formation in one arm causes the ring to appear as a chain. Temecula Grade, Riverside County. Diagrammed in figure 9.—Fig. 5. Two fragments at metaphase in the same plant as figure 4. The smaller fragment is attached to an *M* chromosome by a terminal chiasma, and just below it is a short chromosome from which one or both fragments are derived. Further discussion in the text. The chiasma frequency in this cell is low; in this respect it is more typical than figure 4.—Fig. 6. Bridge-fragment configuration at second anaphase in the same plant as figures 4-5, the result of an inversion. Non-disjunction has taken place at first anaphase in the *D* and *E* chromosomes. Further explanation in the text.

suggestions that may be made at the present time regarding the causes of the distribution of the different types, which must await further evidence for confirmation or disproof.

One is that the present "center of distribution" of the species is also its center of origin, since the structurally homozygous types are more abundant there and absent from the peripheral portions of the range. This suggestion, however, is not supported by the geologic history of the region (Reed, 1933). The oldest land area in the range of the species is in and around San Diego County, where the largest rings are found. This region has been land continuously since the Cretaceous, and there is good reason to believe that *Paeconia*, an ancient group, has inhabited the region uninterruptedly at least since the Oligocene or Miocene epoch. San Luis Obispo and Santa Barbara Counties, now apparently the center of distribution, were inundated during the upper Miocene, along with Monterey County, and in part during the Pliocene. Therefore, it is possible that the species radiated northward from its present center in Santa Barbara County to its present northern limit; but it is very unlikely that the southern portions were colonized in this manner, as the southern portions were probably occupied by *Paeconia* earlier than this present center.

The other suggestion is that some of the higher heterozygotes have colonized those portions of the range which are ecologically more extreme. Thus, the rainfall in San Diego and Riverside Counties is the lowest found within the range of the species, and the species reaches higher altitudes here than elsewhere. In Monterey County, the northern extreme, the reasons for the limits of distribution are obscure, though winter temperatures are slightly lower than they are toward the center of distribution. It can only be said of this region that the existence of some limiting ecological factor is suggested by the fact that the species ends rather abruptly here (Pine Canyon, near King City).

The conditions postulated by Cleland (and by Darlington) for the high survival value of the complete ring include self-pollination, and preservation of heterosis by means of balanced lethals. In *Paeconia californica*, the difficulties of growing the plants (due chiefly to their being long-lived, slow-maturing perennials) have prevented experimentation to show whether there is a balanced-lethal mechanism at work. The presence of such a mechanism is suggested by the occurrence of homogeneous colonies such as the one, described above, at Altadena, but the contrary situation appears to exist in the heterogeneous colonies described. The regular occurrence of cross-rather than self-pollination is suggested by the fact that the colonies are morphologically heterogeneous; plants growing together show numerous individual differences, indicating a considerable degree of heterozygosity in addition to cross pollination. It is expected that evidence will soon be obtained showing definitely whether or not the plants are self-sterile. In any event, field observations of many hundreds of

plants have failed to show any greater degree of hybrid vigor in the ring-forming plants than in the pair-forming ones. Darlington and Gairdner (1937) have pointed out that self-sterility is an aid to the maintenance of interchange heterozygotes before the development of balanced lethals, and this suggestion may apply to *Paeconia californica* if the plants prove to be self-sterile.

The suggestion of Stebbins and Ellerton (1939), that interchanges which increase the size of the ring in *Paeconia* are probably caused by interlocking and subsequent breakage of chromosomes in the prophase of meiosis, seems to the author to be the most acceptable one. Interlocking is rather frequent in both pairs and rings (fig. 3), as also reported by Catcheside (1931) in *Oenothera* and by Sax (1931) in *Rhoeo*. That breakage may occur was also shown by Stebbins and Ellerton, and by Husted (1937). The occurrence of two-chromatid fragments at metaphase provides evidence of such breakage (fig. 5). One of the more striking things about meiosis in *Paeconia* is the relatively small size of the nucleus for the large size of the chromosomes; this fact, added to the marked tendency for pairing to occur only in the terminal portions of the chromosomes in both pairs and rings (Stebbins and Ellerton, 1939), may account for the numerous interchanges. Whether a balanced-lethal mechanism is at work, which tends to stabilize the rings in some cases, is as yet uncertain. The survival of interchange heterozygotes in the species in general is probably due, not to any particular survival value of the structurally heterozygous condition, but merely to the fact that interchanges occur frequently and to the added fact that in a long-lived perennial like *Paeconia*, fertility may be very greatly reduced without significantly affecting the reproductive ability of the species. A vigorous plant may bear a dozen or more flowers with over a hundred anthers per flower; thus the supply of pollen is large even with fertility reduced to 30 per cent, which is the approximate pollen fertility reported by Stebbins and Ellerton, and represents the lowest figure yet found by the author. The limiting factor in seed setting appears to be not ovule fertility, but the small size of the ovary for the size of the seeds; many of the developing seeds are regularly crowded out. In all field observations to date, there appears to be abundant seed set in both pair-forming and ring-forming plants.

Thus, it appears to the author that ring-formation in *Paeconia* does not have the positive selective value that has been adduced for it in *Oenothera*. Its probable causes may be summarized as follows: segmental interchange is favored by the large chromosomes, small nucleus, and terminally localized pairing, a combination of circumstances which favors interlocking and subsequent breakage. The structural hybrids which arise are not selected against, because in a long-lived perennial fertility may be much reduced and still leave ample reproductive ability. Therefore, through the ages, the structural hybridity has gradually accumulated.

SUMMARY

A study of structural hybrids in *Paeonia californica* ($n=5$) has revealed a complete series of interchange heterozygotes, including 5_{II} , $\odot 4$, $\odot 6$, $2 \odot 4$, $\odot 8$, $\odot 6 + \odot 4$, and $\odot 10$. This is the second complete series now known, paralleling the situation in *Oenothera* subg. *Onagra*. In addition, recognition of two of the five pairs in meiosis has made it possible to show differences in the constitution of rings of a given size, and to show alterations in chromosome morphology through unequal translocation. It is shown that there are certain regularities in the geographic distribution of the various types: a tendency is noted for pair-forming types and small rings to be more abundant near the center of the range of the species, and for the larger rings to

be more numerous near the periphery. Tentative suggestions are advanced to explain these regularities, and comparisons are made between the distributional features of *P. californica* and those of *O. iagra*. It is suggested from cytological and distributional evidence that there is no particular survival value associated with the complete ring in *Paeonia*, in contradistinction to *Onagra*, but that the extensive structural hybridity found is due to a combination of cytological circumstances favoring frequent interchange, added to the fact that the plants are long-lived perennials in which even large reduction of fertility does not significantly reduce reproductive ability.

THE MORPHOLOGY OF *RIELLA AFFINIS*. II. DEVELOPMENT OF THE SEX ORGANS, FERTILIZATION, AND DEVELOPMENT OF THE SPOROPHYTE ¹

R. H. Thompson

IN A previous account of the investigation of *Riella affinis* (Thompson, 1941) vegetative development was described. The present paper completes the account of that investigation with the description of sexual development and development of the sporophyte of *Riella affinis*.

DEVELOPMENT OF SEX ORGANS: THE ANTHERIDIUM.—*R. affinis* is homothallic and protandrous. The first antheridia are produced very shortly after the apical cell is established. The mature antheridia lie in notches at irregular intervals along the margin of the wing. The base of the notch, the receptacle, sometimes bears a single antheridium but more fre-

quently two to four antheridia. Each antheridium is surrounded by a flask-shaped involucre (fig. 68a and 68b).

Hofmeister (1854), who was the first to describe antheridial development in *Riella*, held that a marginal cell of the wing produces a vesicular swelling beyond the edge of the wing and that the vesicular portion is cut off at the margin level. This antheridial initial is immediately surrounded by a cellular sheath produced by rapid growth of the cells adjacent to its base. Leitgeb (1879) investigated the same species of *Riella* as Hofmeister, but had only older stages in development of the antheridia. From a study of these he postulated that the antheridial initial and the involucre initials must have been produced simultaneously, and that this came about by two successive divisions of a marginal cell in the plane of the wing. Vrabner (1933) holds that one entire marginal cell of

¹ Received for publication June 10, 1941.

the wing functions as an antheridial initial. The initial divides unequally to form an inner basal cell and an outer cell. Two successive longitudinal divisions of the basal cell, in the plane of the wing, produce a single involucre initial on each side of, and below, the developing antheridium. The antheridial involucre is produced by these two initials together with the two adjacent marginal wing cells. The following account of antheridial development in *R. affinis* confirms Leitgeb's deduction concerning the early stages of development.

The antheridial initial and the primary cells of the involucre are formed from a group of three adjacent marginal cells two or three times removed from the apical cell (fig. 69, Anth.). Each of the three cells divides unequally in the plane of the wing. The larger of the two daughter cells formed by each division then divides in the same manner (fig. 70a, Anth.). This produces a group of nine cells of which the central one is the antheridial initial and the surrounding eight cells are the initial cells of the involucre (fig. 71, 72a).

The antheridial initial enlarges at its outer free end and protrudes slightly above the level of the adjoining involucre initials (fig. 69). It then divides transversely. This division is unequal and produces a rectangular inner cell, the basal cell, and a globose outer cell (fig. 69). Two successive transverse divisions of the outer cell produce a young antheridium which is composed of three superimposed cells, and which is ovoid in shape (fig. 68a, 69). The innermost cell of these three divides transversely to produce the two-celled stalk of the mature antheridium. The two remaining cells produce the capsular portion of the mature antheridium. Each of the two cells, developing into the capsular portion, divides longitudinally and generally in the plane of the wing (fig. 70a, Anth. 3). As a rule the cell nearest the stalk divides first, and further division in this tier precedes that in the outer tier (fig. 70a and b, Anth. 3). Next, each cell in each of the two tiers divides longitudinally but in a plane at right angles to that of the first division (fig. 70b). Each cell of the quadrants thus formed then divides periclinally (fig. 72c and d). These divisions produce eight peripheral cells, which are the primary jacket cells of the antheridium, and eight central cells, which are the primary androgonial cells. The primary androgonial cells enlarge and divide in three planes. Repeated division of the androgonial cells produces a large number of androcyte mother cells (fig. 73). As is the case in most Hepaticae, divisions are simultaneous in each group of

cells derived from a single primary androgonial cell (fig. 73). In the meantime the primary jacket cells divide in two planes so that the growth of the antheridial jacket keeps pace with that of the interior. Chloroplasts appear in the jacket cells very early, but they never become as prominent as those in the involucre and wing cells.

Growth of the involucre is simultaneous with that of the antheridium. The eight involucre initials surrounding the antheridial initial function together as a ring of apical initials. The ring of apical initials successively cuts off seven or eight tiers of derivatives. Each cell in the median tiers produces several daughter cells by longitudinal division. Longitudinal divisions are fewer in the last formed tiers. When the eight apical initials cease dividing they elongate greatly to form the neck of the now flask-shaped involucre (fig. 69b).

During maturation of the involucre cells the chloroplasts in the jacket cells of the antheridium become orange-red. At the same time the walls of the androcyte mother cells begin to gelatinize. Breakdown of the walls continues during division of the androcyte mother cells to form androcytes and during the metamorphosis of these into antherozoids. The coiled antherozoids soon lie free in the viscous fluid within the capsule of the jacket.

Explosive discharge of the antherozoids was observed both in culture and in temporary mounts. This phenomenon is unusual inasmuch as it has only been reported in the case of *Asterella*, *Conocephalum*, *Marchantia*, and *R. helicophylla*. More frequently, however, the antherozoids are exuded in a slow stream through the ruptured apex of the antheridial jacket. They may become active while still within the antheridium or only after they are released.

THE ARCHEGONIUM.—Archegonia are borne on both sides of the adult thallus on the morphologically dorsal side of the rib. In *R. affinis* they are produced in acropetalous succession, generally in series of three to five, and generally during periods alternate with those of antheridial formation in the wing.

An archegonial initial is a wing cell which is generally twice removed from the apical cell and lies in the region of juncture of wing and rib (fig. 32-34, 74, 75). This initial forms a cylindrical protrusion which becomes enlarged and broadly rounded at its tip. Chloroplasts are not evident in the protrusion, and the protoplasm in the apical portion is densely granular. The initial divides transversely, and the wall formed is at the level of the thallus surface. Of

the two daughter cells formed by this division, the short basal cell remains embedded in the tissue at the base of the wing, and the outer cell stands above the thallus surface. The outer cell divides transversely, but unequally, to produce two daughter cells (fig. 75*a* and *b*). The inner, larger daughter cell, which is adjacent to the basal cell, is the primary stalk cell of the archegonium. The sister cell develops into the flask-shaped portion of the archegonium.

The cell producing the flask-shaped portion of the archegonium enlarges and divides longitudinally into two daughter cells of unequal size (fig. 76, 77). The larger of the two daughter cells divides longitudinally and unequally but in a plane anticlinal to that of the first division. The larger of the two cells formed by this division then divides periclinally, so that there is produced a primary axial cell and three peripheral cells (fig. 79*a* and *b*). A longitudinal division of each peripheral cell results in a ring of six jacket initials around the primary axial cell (fig. 72*a* and 72*b*, Arch.). During the longitudinal division of the peripheral cells the primary axial cell also divides, but transversely and unequally. The upper and smaller daughter cell of this division is the primary cover cell (fig. 78). The lower and larger daughter cell is the central cell of the archegonium. In the meantime the primary stalk cell has divided longitudinally and generally in a plane at right angles to that of the first division in its sister cell above (fig. 77).

There is next a nearly simultaneous transverse division of each of the six jacket initials (fig. 80, 81). Each of these divisions is unequal and produces two daughter cells of which the upper one is the smaller. The six upper daughter cells formed by this division of the jacket initials are the neck initials. The six lower daughter cells are the venter initials. Coincident with division of the jacket initials there is an unequal, transverse division of the central cell. The upper daughter cell is the primary canal cell and the lower daughter cell is the primary ventral cell (fig. 81). The nucleus of the latter cell is very large and remains close to the newly formed wall.

During the formation of venter and neck initials each of the two stalk cells divides longitudinally and in a plane at right angles to the wall between the two. The four stalk cells thus formed now divide transversely and unequally (fig. 80, 81). The four upper daughter cells, which are the smaller, constitute the floor of the venter of the archegonium. The four lower daughter cells constitute the archegonial stalk and later produce the archegonial involucre.

The six venter initials divide in two planes and produce the venter of the archegonium. Division of the six neck initials is transverse and produces the neck of the archegonium.

During the development of the venter and neck of the archegonium, the divisions of the primary canal cell and primary ventral cell are completed. The pri-

mary canal cell divides transversely to form two daughter cells (fig. 82-84). Each of these, generally the inner of the two first, also divides transversely, with the result that four neck canal cells are formed (fig. 85, 86). During the divisions that produce the neck canal cells, the primary ventral cell divides transversely and unequally to produce two daughter cells, of which the lower and larger one is the egg cell and the upper and smaller one is the ventral canal cell (fig. 84-86).

The archegonium grows rapidly in size after the completion of the division to form ventral canal cell and egg. During this growth the primary cover cell divides quadrately to form four cover cells at the apex of the archegonium.

Each of the neck canal cells and the ventral canal cell shrinks away from the walls of the neck cells and gradually disintegrates. The egg cell swells considerably and a large amount of the cytoplasm becomes aggregated at the periphery of the nuclear membrane (fig. 87). The nucleus of the egg is very large and contains a dense central body surrounded by a wide hyaline area between it and the nuclear membrane. At maturity of the archegonium the four cover cells swell and separate from each other, leaving the neck of the archegonium open for the entrance of antherozoids.

The mature archegonial involucre of *R. affinis* is ovoid and ornamented with eight wing-like, longitudinal ribs. Of the seventeen species of *Riella*, *R. affinis* is one of the three with such ribs on the involucre.

Vraber (1933) describes in *R. helicophylla* the formation of a massive archegonial stalk. The peripheral cells of the stalk adjacent to the venter of the archegonium function as involucre initials.

In *R. affinis* the archegonial involucre originates from the four stalk cells of the archegonium. At about the time of the formation of neck canal cells, the stalk cells begin to bulge out at the upper end of each cell (fig. 88). Each stalk cell then divides longitudinally to produce two daughter cells, the outer of which is an involucre initial (fig. 87). Each of the four involucre initials functions as an apical cell and successively cuts off three or four derivatives (fig. 89). All but the lowermost of the derivatives divide once in a longitudinal plane. If the egg in the archegonium is not fertilized, there is no further development of the involucre; if the egg is fertilized, each of the four apical cells divides longitudinally to form two apical cells. Each cell in the ring of eight apical cells cuts off several derivatives. A derivative once removed from its apical cell divides longitudinally in a plane parallel to the surface of the involucre. The outer daughter cell by division and redivision contributes to the rib or wing portion of the involucre (fig. 92*a* and *b*, 98-100). Since there are eight longitudinal rows of derivatives, there are generally eight involucre ribs, each a sheet one cell in thickness (fig.

Fig. 93-104, $\times 363$. Sporophyte development.—Fig. 98-101. Development of the involucre.—Fig. 101. Cross section of a young sporophyte and its involucre.—Fig. 103. Cross section of a young sporophyte foot of about the same age as figure 102.—Fig. 104. Fully developed foot.

101). The inner daughter cell, formed by periclinal division of a derivative, by division and redivision in two planes contributes to the body of the involucre. About the time the sporophyte is forming spore mother cells, each apical cell elongates greatly and matures into a papillate terminal cell at the apex of the involucre.

FERTILIZATION.—Fertilization has been observed several times, but all the cases fall into two phases of gametic union. Each of these can be correlated with similar phases in *R. helicophylla* described by Kruch (1890). Each can be compared more exactly with phases described by Rickett (1923) for *Sphaerocarpos Donnellii* Austin. As is the case in *S. Donnellii*, the position of the male nucleus in the egg of *R. affinis* is variable (fig. 90, 91). The earlier of the two phases observed (fig. 90) is similar to that shown in Rickett's figure 4, which he termed the third phase of fertilization. In this phase there is no evidence of chromosome formation. The later phase of gametic union found in *R. affinis* (fig. 91) is similar to Rickett's sixth phase in which the chromosomes have become evident in the male nucleus.

As is the case with other Hepaticae the cells of the venter begin periclinal division shortly after the antherozoid penetrates the egg. Periclinal division continues during the phases leading up to fusion of the gamete nuclei so that by the time of the first division of the zygote the venter is two cells thick throughout (fig. 90–92a).

DEVELOPMENT OF THE SPOROPHYTE.—The mature sporophyte of *Ricella* consists of a globose capsule, a short seta and a bulbous foot. The jacket of the capsule, which is one cell thick, encloses two kinds of cells, spores and nurse cells. The spores at first lie in tetrads, but at maturity lie entirely free from one another.

Hofmeister (1854) states that the first division of the zygote of *R. Reuteri* is transverse and that both daughter cells divide transversely. The two upper cells in the filament of four produce the capsule of a mature sporophyte, and the two lower cells produce the seta and foot. Vrabner (1933) also reports a similar development of the sporophyte in *R. helicophylla*. The first division of the zygote in *R. affinis* is transverse (fig. 92a, 93). Usually there is an elongation of the hypobasal cell and then a transverse division of this cell (fig. 94). Of the filament of three cells thus formed the two upper cells produce the capsular portion of the mature sporophyte and the lowermost produces the seta and foot portion.

In some cases after transverse division of the zygote there is a longitudinal division of both epibasal and hypobasal cells to form a four-celled embryo with quadrately disposed cells (fig. 95). The pair of hypobasal cells then divides transversely (fig. 96). In these six-celled embryos the four upper cells produce the capsule of the mature sporophyte, the two lower cells produce the seta and foot.

If the young embryo is a three-celled filament the two upper cells divide longitudinally, and each

daughter cell also divides longitudinally but in a plane at right angles to that of the preceding division (fig. 97, 98). The embryonic capsule now consists of two superimposed quadrants. Next, each cell of a quadrant divides periclinally to form an outer primary jacket cell and an inner primary archesporial cell. The primary archesporial cells divide successively in three planes to produce a large number of sporogenous cells (fig. 99–102). The primary jacket cells divide successively in two planes and in a very regular sequence. Some of the sporogenous cells enlarge to form spore mother cells each of which then produces a tetrad of spores. The remaining sporogenous cells develop chlorophyll and accumulate starch. These are termed nurse cells and as in the case of those in *Sphaerocarpos Donnellii* (Gross and Allen, 1938), they are four-nucleate.

During the first few divisions of the primary archesporial cells the lowermost cell of the embryo sporophyte divides transversely and successively to form a linear series of four cells (fig. 99, 100). Successive transverse division of each of these increases the number of cells to fifteen or twenty (fig. 102). Further division of the upper five or six cells is in three planes, so that the upper end of the seta becomes broad. Further division of the lower six to ten cells is also in three planes and produces the globose, multicellular foot (fig. 102–104). In between these two regions, the cells divide once or twice longitudinally. The cells of the developing foot enlarge laterally, forming finger-like projections that become insinuated between the cells of the gametophyte tissue (fig. 104).

During the growth of the sporophyte, periclinal division continues in the portion of the venter which surrounds the seta and foot. This portion of the venter becomes three to six cells thick (fig. 98–100). The basal cell of the archegonium and the stalk cells also divide many times (fig. 99). Division in three planes of the basal cell and the adjacent wing and rib cells produces a short stalk that elevates the sporophyte and its involucre above the level of the rib surface.

SUMMARY

The account of the development of the antheridium and the antheridial involucre in *R. affinis* confirms Leitgeb's deduction that these two structures are formed simultaneously.

The development of the archegonium parallels that found in the Marchantiales. The stalk cells not only give rise to the floor of the venter but also produce the initials from which the archegonial involucre develops.

The development of the sporophyte is the same as that in *Sphaerocarpos*, and, as is true in *S. Donnellii*, the nurse cells are four-nucleate.

DRAWING GUIDE FOR ZINC ETCHINGS

Letters, lines, and dots in relation to reduction for the printed page. Top—Reduction to 1/4. Middle—Reduction to 1/2. Bottom—Original size.

Reprinted by permission of the authors from: RIKER, A. J., and REICHA S. RIKER. 1936. *Introduction to research on plant diseases*. 117 p. Published by the Authors, Department of Plant Pathology, University of Wisconsin, Madison, Wis.

Note that thin black lines hold up fairly well in reduction, but that small black dots and small white spaces between black lines or dots may be lost. If placed too close together, dots and lines produce black blotches when the drawing is reduced. Keep the shading rather open. The degree of reduction needs to be known before the drawing is inked in.

Delicate shading may be obtained if the size and spacing of the dots are adjusted to the degree to which the drawing is to be reduced.

POLYPLOIDY IN *SEDUM TERNATUM* MICHX. II. CYTOGEOGRAPHY¹

J. T. Baldwin, Jr.

THIS PAPER gives the geographic occurrence of four chromosome-number races of *Sedum ternatum* Michx. as revealed by routine cytological analysis of the species in the wild. It is one of a series of reports planned on the cytogeography² of North American plants: those on *Galax* L. (Baldwin, 1941), on *Diospyros virginiana* L. (Baldwin and Culp, 1941), and on *Oxydendrum* DC. (Baldwin, 1942) have been written; those on *Leavenworthia* Torr. and on *Sedum pulchellum* Michx. are in preparation. Cytological survey of many species throughout their geographic and ecologic ranges should throw light on such problems as frequency of intraspecific chromosome races; concentration, or lack of concentration, of such races in certain regions and situations; significance of polyploidy; dispersal paths of species; trends in evolution of floras; systematic and phyletic relationships, etc.

Plants of *S. ternatum* were collected from the wild either by the writer or by co-operating individuals (see table 1) and, in most cases, grown in pots at the University of Michigan Botanical Gardens. The chromosomes were usually counted in aceto-carminic smears of roots after fixation in Carnoy's fluid. Such preparations of this species are easily made. Nawa-schin-fixed, crystal-violet-stained sections of roots from some of the collections were studied.

Chromosome numbers were determined for seventy-one collections from locations throughout the

range of the species (table 1 and map 1): eleven collections were diploid— $2n=16$ (fig. 1); two, triploid³— $2n=24$ (fig. 2); fifty-seven, tetraploid— $2n=32$ (fig. 3); one, hexaploid— $2n=48$ (fig. 4). Diploid and tetraploid plants have been previously reported in this species (Baldwin, 1936).

Figure 5 shows the distribution of *S. ternatum* as known to the writer by collections investigated cytologically or by specimens examined by him in certain herbaria.⁴ The map reveals various things about the geography of the races within this species: the diploid has been found in a relatively restricted area in southern West Virginia, southwestern Virginia, and eastern Kentucky; the tetraploid radiates from that area throughout the range of the species—to New York, Michigan, Indiana, Tennessee, Alabama, and North Carolina; the triploid was collected in West Virginia in the region where both the diploid and tetraploid occur and in North Carolina where only the tetraploid is known, but where the diploid might be expected to occur; and the hexaploid was discovered at only one station—near Tuscaloosa, Alabama, approximately the southern limit of the species, and in the vicinity of the tetraploid. Presumably the diploid is primitive, and the other races are derived. The area of the diploid is accordingly the center from which the species has spread in perimetric fashion. It is logical to conclude that the several races are not isolated genetically: existence in nature of the trip-

³ The somatic number of the triploid may be designated as $2n$ or $3x$; of the tetraploid, as $2n$ or $4x$, etc.

⁴ United States National Herbarium, Gray Herbarium, herbaria of the New York Botanical Garden, of the Missouri Botanical Garden, of Cornell University, Duke University, West Virginia University, University of Georgia, University of Kentucky, University of Michigan, University of Tennessee, and private herbarium of Charles C. Deam. Appreciation is here expressed for the privilege of studying these specimens.

loid race and its physical proximity to both the diploid and tetraploid races, as well as the discontinuous distribution of the triploid, support this conclusion. All the races maintain themselves vegetatively; it has not yet been determined whether or not they all produce good seed.

There can be no question but that these races belong to a single species: they quite obviously do. As pointed out by Wherry (1935), this is the only species of *Sedum* in the eastern United States "concerning which no taxonomic difficulties have arisen, its broad obovate leaves consistently whorled in threes being highly distinctive." The different collections, under uniform conditions in the greenhouse, vary considerably in appearance. Yet the four chromosome-number races are not readily separable except by cytological study; an attempt will be made to distinguish them by statistical measurement. However, during the summer of 1941, most of the tetraploid plants and the triploid from Lewisburg, West Virginia, were more resistant than the other collections to the attack of a fungus of undetermined nature.

If glaciation has, in some cases, as perhaps in *S. ternatum*, induced polyploidy, two explanations for such influence may be suggested. One, temperature changes might so alter the viscosity of the protoplasm during nuclear division that the precise mechanism of the division would be upset. Two, glacial movement would continually create new ecological situations into which a species might migrate, and, there, representatives from different parts of the specific

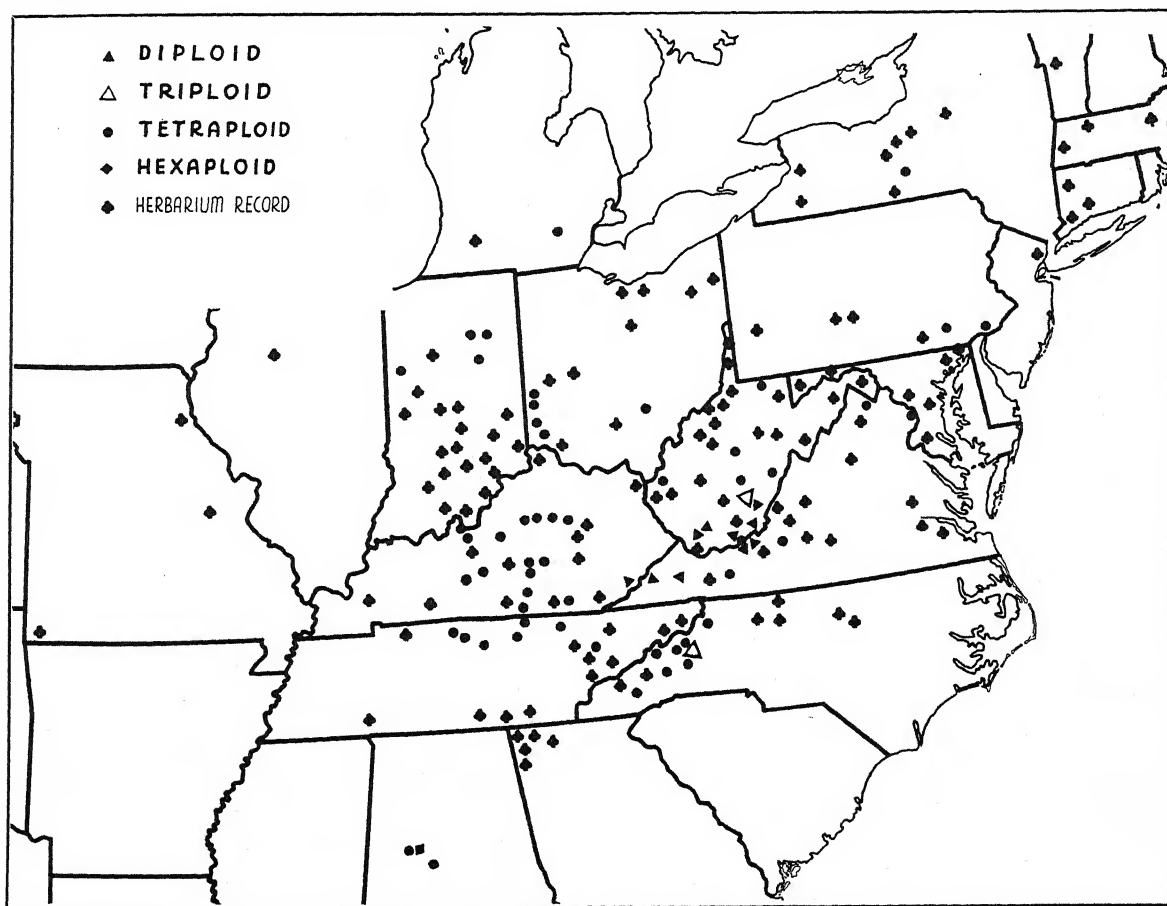

Fig. 5. Distribution of *S. ternatum* from Massachusetts to Missouri and Alabama, as based on herbarium specimens and on collections for cytological study.

range, with chromosomes differentially rearranged, might be brought together to produce polyploid individuals through hybridization.

SUMMARY

Four chromosome-number races of *S. ternatum* Michx. are known in the wild: $2n=16$ (diploid), $2n=24$ (triploid), $2n=32$ (tetraploid), and $2n=48$ (hexaploid).

Geography of the races was determined on the basis of cytological study of seventy-one collections of plants from representative points in the specific area (map 1 and table 1). The diploid, and supposedly primitive, race (eleven collections) was found in a restricted region in West Virginia, Kentucky, and Virginia. The tetraploid (fifty-seven collections) is widespread and radiates from the limited region of the diploid as a center. The triploid (two collections) seemingly has a discontinuous distribution; it was found in West Virginia near both the diploid and the tetraploid races and in North Carolina where both these other races may be expected. The hexaploid (one collection) was found near Tuscaloosa, Alabama, at the southern edge of the specific range and near the tetraploid race.

The several races are apparently not genetically isolated, indications being that the triploid arises through natural hybridization of diploid and tetraploid plants. All the races can maintain themselves vegetatively.

Specimens of *S. ternatum* from different localities often differ much, but it has not been possible, except by cytological means, to draw ready lines of separation between the chromosome-number races.

ALTERATION OF POTATO STARCH GRAIN STRUCTURE UNDER THE INFLUENCE OF DISEASE¹

D. B. O. Savile

IN 1939, during the examination of potato tubers that showed rusty internal flecks seemingly caused by a virus, the identity of which is still in doubt, it was found that a high proportion of the starch grains in cells adjacent to the necrotic areas were distinctly abnormal in form. In view of its possible diagnostic value, the unusual appearance of these grains encouraged an investigation of their origin.

As a pathologist's tool the phenomenon has proved disappointing; for malformed grains have been detected in specimens of a variety of fungous, virous or environmental disorders, though never in the abundance that was seen in the original material. Furthermore, when this necrosis originated in storage the malformed grains were found to be far less plentiful than in specimens submitted at digging time. Botanically, however, these abnormal grains are of considerable interest, for they are evidently the visible results of abnormal function of the leucoplasts that lay them down.

It may be well to emphasize at the outset that these grains are not eroded by hydrolysis. Cell division and cork formation occur at the edges of the necrotic areas, as is frequently the case in injured tissue, and in the dividing cells there is, as always, starch hydrolysis; but the partly hydrolyzed grains, examples

of which are shown in figure 6, are pitted and tunneled precisely like similar grains in normal tubers. The malformed grains, illustrated in figures 1, 3, 4, and 5, are markedly different in appearance. It may be noted that the two small grains at the right in figure 6 are pointed at one end, and it is possible that, in addition to being partly hydrolyzed, they are slightly malformed.

It is not only the leucoplasts that behave abnormally. Nuclear divisions are frequent, but they are not always the regular divisions connected with phellogen formation. Often three, four, or even five nuclei are seen in a single cell. Figure 2 shows a small binucleate cell not connected with any phellogen. Owing to the considerable depth of focus required, it is seldom possible to show more than two nuclei in a photograph. Figure 4 is from a camera-lucida drawing of a pentanucleate cell. It will be seen that the nuclei differ considerably in size, their appearance suggesting the result of fragmentation rather than typical mitosis.

It should be noted that the grains close to the nuclei in figures 1 and 4 (i.e., those last formed) are particularly irregular, whereas those further away are usually normal. This distribution was found to be general and indicates a progressive degeneration within the cell.

An examination of the moderately abnormal grains, many of which resemble in form nothing so much as dipterous larvae (fig. 5, b and c), indicates

¹ Received for publication November 12, 1941.

Contribution No. 684 from the Division of Botany and Plant Pathology, Science Service, Department of Agriculture, Ottawa, Canada.

the way in which they are formed. The grains shown in figure 5 were drawn under crossed nicols in order to show clearly the position of the hilum. The leucoplast appears to become increasingly degenerate during the formation of the grain, for the hilum is close to the more normal end. It would seem that, under the influence of some toxic material (possibly in this case the virus, but probably sometimes a degradation product from adjacent dead cells), the leucoplast either loses much of its elasticity or suffers from

same periodic deposition that is observable in normal grains, but it is possible that they represent merely a spasmodic withdrawal of the degenerating leucoplast.

The abundance of abnormal grains in tubers showing necrosis at harvest time and their scarcity in tubers that became necrotic during the winter are further evidence, should any be required, that these grains are truly malformed and are not normal grains that have been eroded in some novel manner. However, small numbers of such grains have been seen, for example, in tubers invaded by the late blight fungus (*Phytophthora infestans*). In such material it is almost certain that the tubers were still normal when starch formation ceased with the death of the plant. It, therefore, seems probable that when starch

Fig. 1-3. All figures from unstained freehand sections and approximately $\times 600$.—Fig. 1. Parenchyma cell, showing several malformed grains close to the nucleus.—Fig. 2. Small binucleate cell, not part of a phellogen.—Fig. 3. Severely malformed grain.

some surface tension effect. The result of the change, whatever its nature, is the rupturing of the leucoplast on the thin side, where the hilum is closest to the surface of the grain. Once ruptured, the leucoplast withdraws to the opposite side of the grain. Succeeding starch deposition takes the form of caps, one upon another, at this part of the grain.

Sometimes the plastid remains normal until late in the formation of the grain and then degenerates abruptly as at figure 5a; at others degeneration proceeds more gradually with the result that several successive depositions are of nearly equal size (fig. 5b). Severely affected grains seem often to be the products of leucoplasts that are abnormal from the start of deposition. Such grains, which are often pointed at both ends like that in figure 3 and that marked "x" in figure 4, show no dark cross under crossed nicols; but it is seen, from the passage of the dark bands across them when they are centered and the stage is rotated, that the hilum is terminal or virtually so. The extremely small abnormal grains have no readily observable structure, but they, like the larger ones, stain quite as deeply with iodine as do the normal grains.

It seems probable that the "segments" that give the grains their larva-like appearance are due to the

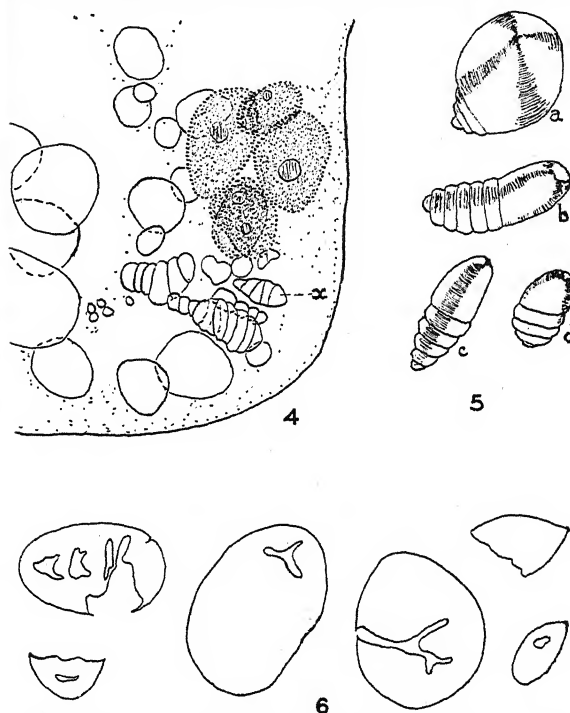

Fig. 4-6. Camera-lucida drawings, approximately $\times 600$.—Fig. 4. Part of pentanucleate cell with malformed grains close to the nuclei.—Fig. 5. Malformed grains viewed under crossed nicols, showing position of hilum near the most normal side.—Fig. 6. Partly hydrolyzed grains, in cells near phellogen, for comparison with malformed grains.

is hydrolyzed, as in the formation of a phellogen, some of the resulting sugar is not used as a source of energy but is transported to other cells and re-formed into starch.

SUMMARY

The occurrence of malformed starch grains in diseased potato tubers is described; it is suggested that their formation is attributable to an altered physical state of the leucoplasts. Associated nuclear abnormalities are also described.

STRUCTURE OF THE APICAL MERISTEM AND DEVELOPMENT OF THE FOLIAGE LEAVES OF *CUNNINGHAMIA LANCEOLATA*¹

G. L. Cross

THE PRESENT paper is the fourth in a series dealing with the structure and development of the shoot apices and foliage leaves in the genera of the Taxodiaceae. The results obtained thus far (Cross, 1939, 1940, 1941) indicate that comprehensive information concerning the various genera in this family may be of aid in understanding the evolutionary processes

per cent commercial formalin and 6 per cent glacial acetic acid, made up in 70 per cent ethyl alcohol. Tertiary butyl alcohol was used for dehydrating and clearing, and the materials were embedded in "Tissue Mat." Sections were cut 8–10 μ in thickness at 65° F., and were stained with safranin and fast green (Cross, 1937). The illustrations were prepared as described in previous papers (Cross, 1939, 1940).

GENERAL FEATURES OF THE VEGETATIVE SHOOT.—

The vegetative shoots of *Cunninghamia lanceolata* (Lamb.) Hook. consist of sturdy axes upon which the leaves are borne in a close spiral (fig. 1). The leaves remain on the stems for many years and at maturity are exceedingly leathery and sharp-pointed. They are reported to vary from 3 to 7 cm. in length (Pilger, 1926), but in the material available to the present writer none longer than 6 cm. was found. With the exception of *Sciadopitys* no other genus of the Taxodiaceae has leaves as long. There are lateral and terminal buds which remain dormant during the colder months; however, bud scales, although associated with strobili, do not occur on the vegetative shoots. All the leaves are of the same general form, viz., flattened linear-lanceolate, with minutely serrate margins, but those forming the outer constituents of resting buds are very short and scale-like. The limits of each recent yearly growth increment of the shoot can be determined by noting the position of these shorter leaves on the shoot axis (fig. 1).

STRUCTURE OF THE SHOOT APEX.—Strasburger (1872) referred to the shoot apex of *Cunninghamia* in connection with his work on *Araucaria brasiliana*. After describing a distinct protoderm, periblem, and plerome for the shoot apex of *Araucaria*, Strasburger wrote (1872, p. 325): "Annähernd ebenso wie *Araucaria brasiliana* verhält sich auch eine andere untersuchte Art, die *Araucaria Cunninghami* und in weiterer Folge auch *Dammara* und *Cunninghamia*." It is clear from Strasburger's discussion that he believed the apical meristem of *Cunninghamia* to be highly differentiated and stratified as in *Araucaria*. Perhaps it should be emphasized that the results of the present study are not in agreement with Strasburger's account. On the contrary, as is shown later, the shoot apex of *Cunninghamia* is the least stratified of any of the investigated genera of the Taxodiaceae, and possibly it may prove to be the primitive "type" in the family. This preliminary statement can be confirmed quickly by a casual observation of figures 2b to 10c, in which a zonation reminiscent of that described for seedlings of *Cycas revoluta* (Foster, 1939), is indicated.

In contrast to the hemispherical shoot apices of *Taxodium* (Cross, 1939) and *Cryptomeria* (Cross, 1941) the apical meristem of *Cunninghamia* is somewhat conical, and appears parabolic in longisection (fig. 3, 4, 8, 9, 10a, 10b). The apex is covered with a

Fig. 1. Vegetative branchlets of *Cunninghamia*. $\times \frac{1}{2}$.

that have produced the highly specialized shoot apices found in modern angiosperms. Materials of all of the genera of the Taxodiaceae except *Glyptostrobus* have been assembled, and it is hoped that shoots of that genus may be obtained at an early date.

MATERIALS AND METHODS.—Materials were collected at weekly intervals during April and May of 1941 from young trees growing in a nursery² six miles south of Norman, Oklahoma. All materials were fixed under reduced pressure in a mixture of 5

¹ Received for publication November 24, 1941.

Contribution from the Botanical Laboratory, University of Oklahoma, No. 67. Publication was assisted by a grant from the Faculty Research Fund of the University of Oklahoma.

well-developed cuticle, detached remnants of which may be seen to the left of the tip in figure 10a. There is some seasonal variation in form, although this feature is not as well marked as it appears to be in some of the *Abietaceae* (Korody, 1937). In the winter condition the height (vertical distance of tip above axil of youngest leaf) averages about $50\ \mu$ (fig. 3). When active growth is resumed in the spring the height increases rapidly to about $80\ \mu$ (fig. 4, 10a). The average diameter of 45 apices (measured in a plane equidistant from the summit of the axis and the axil of the youngest foliar primordium) is $180\ \mu$. From this it can be seen that the shoot apex of *Cunninghamia* is

divisions remain as apical initials, and the inner derivatives augment the subapical portion of the meristem. The apical initials are often conspicuously larger than the cells of the subapical portion (fig. 10a, 10b), and the cellular patterns represented in figures 8 and 9 provide some evidence that anticlinal and periclinal divisions occur with approximately equal frequency. This is in contrast with the situation reported for the apices of the deciduous shoots of *Taxodium* and the shoots of *Cryptomeria*, for in these genera periclinal divisions in the surface layer of the apical meristem occur only infrequently, and are restricted to the extreme summit of the meristem.

generally larger than that of *Cryptomeria* (average width $90\ \mu$) but somewhat smaller than that of *Taxodium* (140 – $170\ \mu$ in width).

The surface layer of the apical meristem.—The surface layer of the shoot apex may be divided into two regions or growth zones (fig. 2b, zones 1 and 2). Zone 1, which is located at the summit and upper shoulders of the meristem, consists of a single tier of self-perpetuating apical initials which divide both periclinally and anticlinally (fig. 8, 9, 10a, 10b). All of the cells of the shoot are derived ultimately from this tier of apical initials. Zone 2, located on the lower shoulders and flanks, consists of a layer of cells in which periclinal divisions do not occur. The cells of this layer produce only the epidermal portions of the shoot, and, therefore, they may be regarded as a protoderm. These structural features are well illustrated by figure 3, which represents a nearly median longisection of a shoot apex in the winter condition. Even in the absence of mitotic figures, it is evident in the illustration that periclinal divisions have occurred abundantly in the surface cells at the summit (zone 1) but not in those of the lower shoulders and flanks (zone 2). Similarly, in figures 4, 5, 7, 8, 9, and 10b, prepared from expanding shoots, groups of cells that have divided periclinally may be distinguished at the summit and upper shoulders of the meristem. The outer derivatives resulting from such periclinal

Figures 6a, 6b, and 6c, drawn from transections of a shoot apex cut respectively at 8, 16, and $24\ \mu$ below the tip, will be of aid in understanding the structure of the apical initials and their inner derivatives. Figure 6a represents two apical initials and all portions of the surrounding cells that were visible in the section. Figure 6b represents the proximal portions of the two apical initials shown in figure 6a, a third apical initial, and several genetically related groups produced by anticlinal divisions in other apical initials. Figure 6c represents several genetically related groups (delimited by heavy lines) which have been formed by the inner derivatives of apical initials.

From a comparative point of view it should be emphasized that the apical initials of *Cunninghamia*, although lesser in number, resemble closely those of seedlings of *Cycas* (Foster, 1939). They are similar also to the apical initials of some genera of the *Abietaceae* (Korody, 1937). However, the presence of a protoderm on the lower shoulders and flanks of the shoot apex of *Cunninghamia* is a feature which contrasts sharply with these other genera.

The subapical portions of the shoot apex.—The subapical region consists of three growth zones (fig. 2b, zones 3, 4, and 5) which are distinguished by differences in position, plane of cellular division, and extent of vacuolation. Zone 3, derived directly from the apical initials of zone 1, consists of a group of

subapical mother cells (fig. 3, 4, 9, 10a, 10b, 10c) which are equivalent in position and function to the "subterminal mother cells" of *Cycas* (Foster, 1939) and to the central embryonic cells of *Taxodium* (Cross, 1939) and *Cryptomeria* (Cross, 1941). Lateral and basal derivatives of the subapical mother cells contribute to zones 4 and 5, respectively (fig. 2b, 3, 4, 8, 9), and these zones in turn produce all of the internal portions of the shoot. The subapical mother cells, except for their occasional smaller size (fig. 8, 9, 10a), are not easily distinguished cytologically from the apical initials. Although the cellular patterns in most of the apices examined gave positive evidence of recent divisions, mitotic figures were not often found, regardless of the time of day at which collections were made. However, because mitotic figures were abundant in young leaves (fig. 9, 11, 12, 13), it has been concluded that the shoots were in an actively growing condition. Possibly the puzzling absence of dividing cells in zone 3 (and other zones as well) may be correlated with periodicity of growth. Unfortunately, by the time the writer had found time to section the material, the growing season had ended, and additional collections could not be made to settle this point.

Zone 3 varies considerably with respect to the arrangement of its cells, but figures 4 and 9 represent conditions most commonly observed in the forty-five apices that were studied. In figure 4 the subapical zone is seen to consist of several groups of genetically related cells, delimited by heavy lines. Each of these groups of genetically related cells has been formed from an inner derivative of one of the apical initials. This was shown clearly in the stained sections, for the outline of the mother cell of each group could be distinguished easily because of its greater thickness. In figure 9 the arrangement of the cells in the subapical zone is somewhat different. Here some of the derivatives of the apical initials have enlarged, and one apparently has experienced a series of transverse divisions which has produced a vertical chain of four cells through the center of the zone. However, such examples of polarized growth are not of frequent occurrence, and usually the subapical mother cells divide irregularly in vertical, horizontal, and oblique planes (fig. 10c). The cellular pattern is often suggestive of a block meristem (Schüpp, 1926), and it conforms generally to the description given by Foster (1939) for the "subterminal mother cells" of *Cycas*.

of expanding shoot about 6μ from median, showing plasmolyzed subapical mother cells.

Zone 4 is a peripheral ring or cylinder of meristematic tissue, consisting of from two to four peripheral layers of densely staining cells, and located beneath the shoulders and flanks of the shoot apex. It is derived directly from the subapical mother cells (zone 3) and its derivatives produce all of the shoot except the pith and the epidermal portions. Because zones 3 and 4 merge into one another a sharp line of demarcation may not be drawn between them. However, in contrast to zone 3 anticlinal cellular divisions predominate in zone 4, and the cellular pattern as seen in longisection often appears somewhat stratified (fig. 4, 10b, 10c). However, this characteristic is not so well marked in *Cunninghamia* as it is in the meristematic flanks of *Taxodium* and *Cryptomeria*, and zone 4 is often very suggestive of the unstratified peripheral tissue of *Cycas* (compare figures 10a and 10b with Foster's figures 2 and 5, 1939).

Zone 5 consists of a core of pith mother cells which diverge from the basal portion of zone 3. The cells of this zone are arranged in irregular vertical rows. They are somewhat larger and more highly vacuolated than are those of zone 4, and they do not stain as densely. They enlarge very gradually as their distance from the summit is increased (fig. 9, 10a, 10b), in contrast to the pith mother cells of *Taxodium* and *Cryptomeria* (Cross, 1939, 1941) which often enlarge abruptly within three or four layers beneath the summit of the apical meristem. Except in the case of certain dormant apices (fig. 3), vertical files of cells suggestive of a rib meristem (Schüepp, 1926) were not observed. On the contrary the pith mother cells divide by the insertion of vertical as well as horizontal walls, and the lateral limits of the zone are, therefore, poorly defined (fig. 10a). The heavy lines which delimit zones 4 and 5 in the illustrations are drawn arbitrarily for the reader's convenience. The highly variable cellular pattern of the pith initials, together with their very gradual basipetal differentiation, suggest Foster's description of the central tissue in seedlings of *Cycas*.

It would seem that Strasburger's brief comment concerning apical meristem in *Cunninghamia* must have been based upon the study of poorly fixed material or upon non-median sections. The work of that period was done necessarily without the aid of modern technique, and in addition, botanical thought, insofar as it pertained to shoot apices, was dominated by the concepts of Hanstein (1868). A reinvestigation of much of the earlier work might prove profitable.

ONTOGENY OF THE FOLIAGE LEAF.—In general the origin and development of the foliage leaves of *Cunninghamia* are much like the corresponding processes

in *Taxodium* and *Cryptomeria*. However, there are enough differences to justify a reasonably comprehensive treatment. The following description pertains only to the large foliage leaves. The small, scale-like leaves that constitute the outer components of vegetative buds and the bud scales that enclose the strobili were not studied.

Initiation and early vertical growth of the primordium.—Foliage leaves are initiated in the flanks of the apical meristem from 80 to 100 μ below the summit. As in *Taxodium* and *Cryptomeria* the surface layer or protoderm does not divide periclinally during foliar initiation and forms, therefore, only the epidermal portions of the leaf. This contrasts significantly with the situation reported for other perhaps more primitive vascular plants, such as *Abies*, *Picea*, and *Pinus* (Korody, 1937), various other gymnosperms (Strasburger, 1872), and *Lycopodium* (Hartel, 1938), all of which have shoot apices that resemble those of *Cunninghamia* in that they do not have a discrete surface layer (protoderm or dermatogen) at the summits of their shoot apices. In *Abies*, *Picea*, *Pinus*, *Lycopodium*, and the genera of the Abietaceae investigated by Strasburger, periclinal divisions occur abundantly in the epidermal layer during foliar initiation, and the epidermal layer thereby contributes substantially to the internal portions of the primordium.

In *Cunninghamia* the initial elevation of a foliar primordium results from the lateral elongation of a number of cells located in the second and third layers of the primordium (fig. 11). This elongation usually is accompanied by considerable meristematic activity in the surface layer (fig. 11) and in the deep-lying cells (fig. 12), so that at least four layers of cells may be regarded as participating in the process of foliar initiation. At a very early stage in development the young leaf curves upward and begins to grow vertically. Figure 12 represents a young leaf just beginning upward curvature and vertical growth. In this figure two cells, conspicuous for their larger size, may be seen at the apex of the primordium. These are the apical initials, and they resemble closely the apical initials of the foliar primordia described for *Taxodium* (Cross, 1940) and *Cryptomeria* (Cross, 1941). Immediately beneath the apical initials in figure 12 are cells which correspond in position to the subapical initials in the young leaves of *Taxodium* and *Cryptomeria*. However, as is shown later, the subapical cells of the leaf of *Cunninghamia* are much less active mitotically than are those of the related genera.

A consideration of figures 10, 13, and 14, in the order given, should be of aid in understanding the

Fig. 11–18.—Fig. 11. Portion of median longisection of shoot apex showing initiation of leaf; *pc*, provascular tissue.—Fig. 12. vertical growth of the young leaf. In figure 10, which was drawn from a primordium about $75\ \mu$ high (measuring from the tip to the axil of the primordium), one of the apical initials is dividing anticlinally. The "subapical initials" are inactive mitotically, but lower in the primordium several cells in various stages of mitosis may be seen. Study of a great many leaves in similar stages of development has convinced the writer that early vertical growth of the foliar primordium is due to general mitotic activity throughout the organ, and is not a result of the mitoses of localized groups of cells, such as subapical initials. As a matter of fact, a subapical cell of the leaf of *Cunninghamia* was seen in a mitotic condition only once during the entire investigation. In figure 13, drawn from a median section of a foliar primordium about $160\ \mu$ in height, the subapical cells are represented in an early stage of differentiation as evidenced by their possession of densely-staining clumps of ergastic material. Lower in the same figure mitotic figures may be seen. The subepidermal cells of the adaxial and abaxial surfaces have begun to elongate in the distal portions of the primordium, and apparently these elongating cells do not experience further mitotic activity. In leaves of this height a tendency to restrict meristematic activity to the proximal half is quite noticeable. The tendency is expressed to a greater extent in figure 14, drawn from a primordium about $310\ \mu$ in height. Here the subapical cells are elongated conspicuously, and all of the cells of the distal half show evidence of elongation. However, these elongating cells are still potentially meristematic as is shown by the metaphase in the distal part of the leaf. Elongation in the subepidermal cells is especially marked and shows evidence of basipetal progression. From the smaller size of the cells, and the frequency of mitotic figures in the basal part of the leaf represented in figure 14, it is clear that meristematic activity is largely restricted to this region. After the $300\ \mu$ -stage, further increase in height, except that which is attained by continued cellular elongation, is largely a result of mitotic divisions in the lower one-half or one-third of the young leaf. However, the apical initials remain meristematic until the leaf is at least 1 mm. in height, and often one of them may divide at this late stage in such a plane as to produce a terminal, unicellular hair (fig. 19).

It is convenient to mention at this time that the provascular tissue of the young leaf differentiates acropetally. The provascular tissue of the subjacent internode is distinguishable at the time the foliar primordium is initiated (fig. 11). Probably it is continuous from the beginning with the provascular tissue of older portions of the shoot axis, but this could not be demonstrated with certainty. In any event, as far as the foliar primordia are concerned the provascular tissue differentiates in a strictly acropetal di-

Fig. 19-21.—Median longisections from various levels of foliar primordium $1,000\ \mu$ high; *pc*, provascular tissue; *rc*, median resin canal. $\times 330$.

rection (fig. 10–14). A similar situation has been reported by Crafts (1940) for the related genus *Sequoia*.

Lateral growth of the primordium.—During the earlier developmental stages the primordium is generally elliptical as seen in transections taken from various levels (fig. 15–17), although the adaxial surface may appear somewhat flattened in the proximal portions (fig. 15). Until a height of 200–250 μ is attained, only the median or axial portion of the mature leaf is represented. The origin of the lateral, photosynthetic portions occurs essentially as described for *Cryptomeria* (Cross, 1941). Some evidence of localized marginal and submarginal activity is supplied by figure 15, although a single row of submarginal initials such as occurs in the young leaves of *Taxodium* was not observed. Rather the young leaf appears to grow laterally as a result of the mitotic activity of submarginal strands of cells. Derivatives of the submarginal cells continue to divide and form genetically related groups of cells, which are often arranged in rows (fig. 15, 16) parallel with a line joining the vein and margin of the primordium. Lateral growth of this kind is restricted to the central and basal portions of the primordium (fig. 15, 16). It does not occur in the early maturing apex (fig. 17).

Although a plate meristem is not formed (Schüëpp, 1926), lateral extension through cellular divisions may occur until the leaf has attained a width of approximately 450 μ . The later phases of lateral extension, during which a final width of approximately 2.2 mm. is attained, are the result of cellular enlargement exclusively. The absence of a plate meristem in the foliar primordia of *Cunninghamia* may be correlated with the relatively narrow width of the mature leaf.

Many of the marginal initials enlarge conspicuously when the young leaf has attained a height of from 500 to 1,000 μ (fig. 18; Plate I, fig. 5). These enlarged initials, by anticlinal divisions, may contribute to the epidermal layer on either surface of the leaf (fig. 18). Ultimately, during maturation, many of them become mother cells of curious, marginal epidermal hairs (fig. 32, 33) which give the mature leaf a serrulate appearance.

Increase in radial thickness and differentiation of the axial portion.—The axial portion of the primordium does not increase markedly in radial thickness. Primordia 150 μ in height usually have a maximum radial thickness of 90 to 100 μ . As the height increases to 1,000 μ the radial thickness increases only to 140 or 150 μ . Therefore, a conspicuous midrib such as is characteristic of immature leaves of *Taxodium* and *Cryptomeria* does not develop. No indications of a localized adaxial meristem were observed; increase in radial thickness is due, first, to general meristematic activity throughout the axial portion and, finally, to cellular enlargement. The failure of an adaxial meristem has been noted also for *Taxodium* and *Cryptomeria*, and may be correlated with the fact that a petiole is not differentiated in the leaves of these genera.

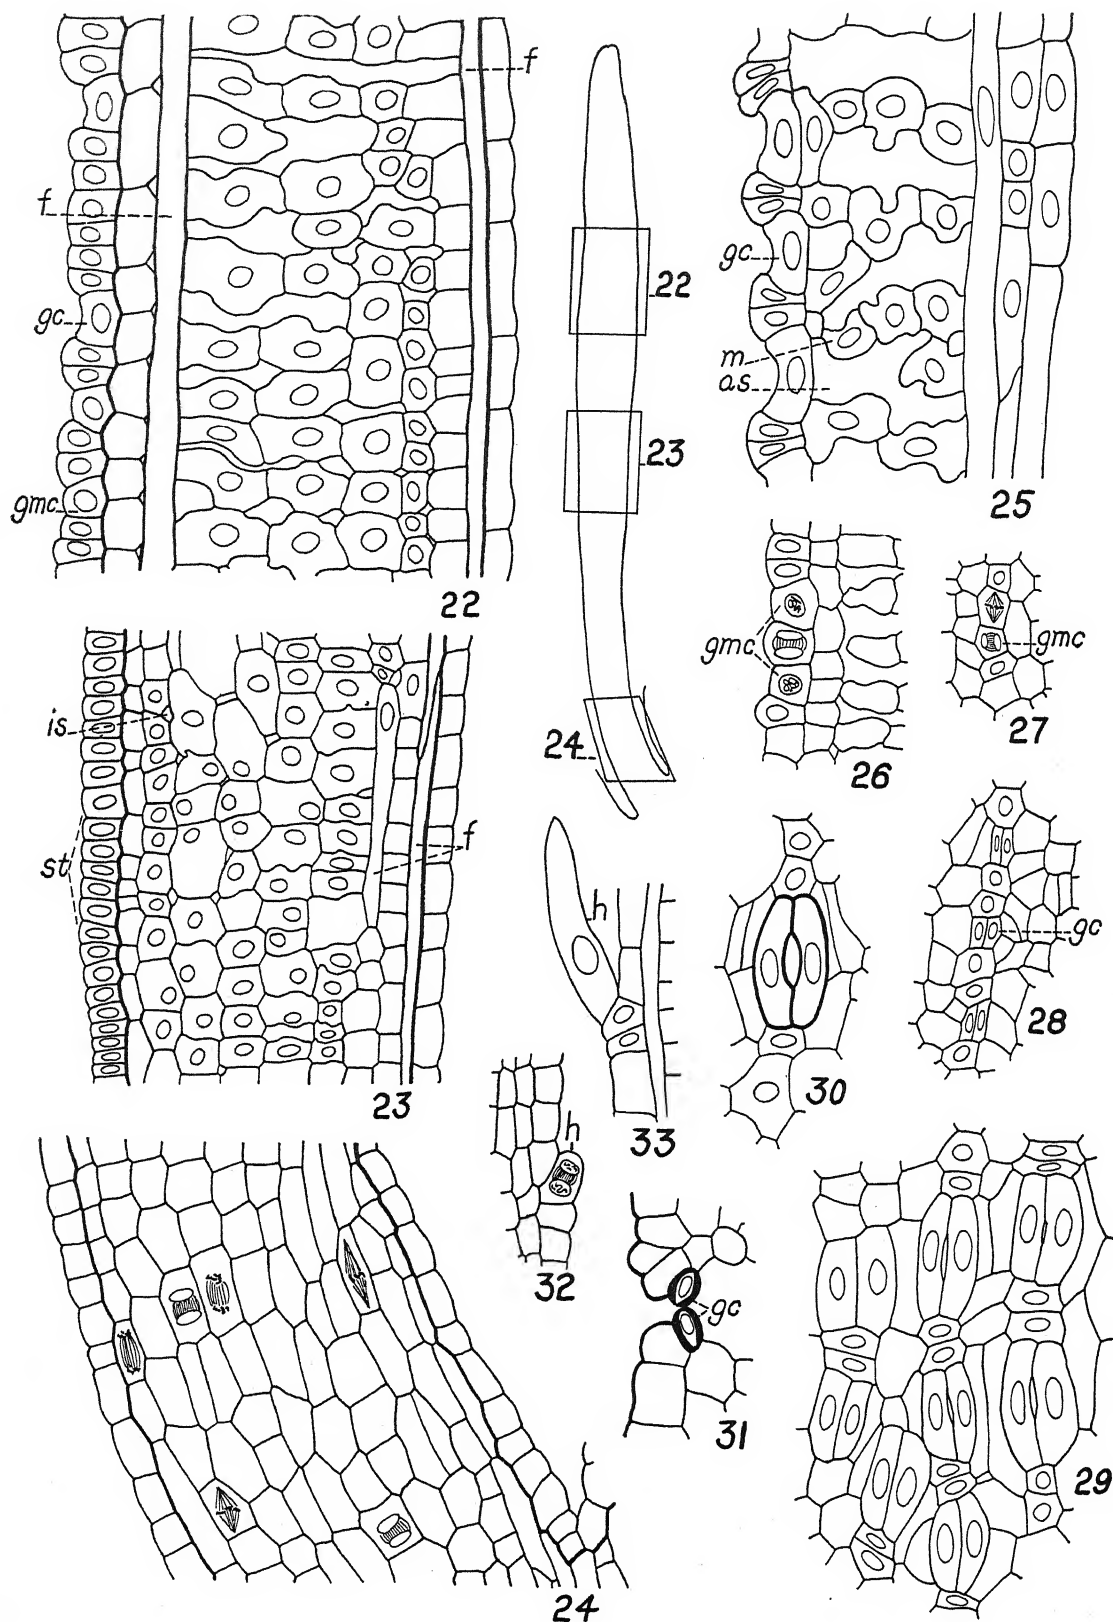

As mentioned earlier, the provascular tissue differentiates acropetally into the base of the primordium, where it may be distinguished easily when the organ is 150 μ in height. The median resin canal appears between the provascular tissue and the abaxial epidermis when the primordium is about 400 or 500 μ in height. The details of its origin and development are in general as described for *Taxodium* and *Cryptomeria*, but unlike these two latter genera the median resin canal of *Cunninghamia* does not end blindly in the cortex of the internode below but anastomoses with the resin canals of other leaves thus forming a continuous system.

Differentiation of the apex of the axial portion may be noticed as early as the 150 μ -stage (fig. 13) when the subapical cells stain densely because of their ergastic contents. Subsequently, the subapical cells begin to elongate (fig. 14). The subepidermal cells of both surfaces of the young leaf elongate similarly, beginning near the apex of the organ and proceeding basipetally. The elongating cells increase enormously in length, thrusting the apex of the leaf upward and forming a slender, tapering tip, the basal limit of which may be distinguished by its constricted appearance (fig. 14, 19, 20). The epidermal cells also elongate somewhat during the process.

Thus, the first cells that become mitotically inactive in the young leaf are the subapical cells. Starting at the subapex, differentiation in the form of cellular elongation proceeds basipetally in the subepidermal portions of the leaf axis until all of the subepidermal cells of the axial portion become greatly elongated. At maturity these subepidermal cells become fibers. The resin canal and provascular tissue do not differentiate in the constricted apical portion of the leaf.

Vertical growth and differentiation of the lateral or laminar portions.—The wing-like lateral portions are initiated when the primordium is from 200 to 250 μ in height, and for some time after initiation lateral and vertical growth occurs simultaneously as a result of cellular divisions. During this period of development, while the young leaf grows to a height of from 1,000 to 2,000 μ , cellular divisions occur in diverse planes throughout the lateral, laminar portions. However, growth in width by cellular division ceases early in ontogeny. Thereafter, the cells of the laminar portion (the axial portion as well) divide almost exclusively by the insertion of walls perpendicular to the longitudinal axis of the leaf. This results in the production of longitudinally oriented rows of cells (fig. 22–24) which have the appearance and structural features of a rib meristem (Schüëpp, 1926). The same condition obtains in *Cryptomeria* and to a very marked extent in *Taxodium*, where the tissues of the lamina are highly stratified because of the extraordinary lengths of the chains of cells.

Differentiation in the laminar portions is initiated in the distal regions near the tip of the leaf and proceeds basipetally. The main features of differentiation are described in the following paragraphs.

The epidermal cells of the adaxial surface cease dividing and elongate vertically until they are two or three times their original length. In the abaxial epidermis cellular elongation occurs also but is restricted to three vertical strips, one over the axial region or midvein and one near each margin of the young leaf. This leaves two strips of mitotically active epidermal cells, one on each side of the midvein and occupying much of the area between the midvein and leaf margin (Plate I, fig. 4). These actively dividing strips of cells ultimately produce rows of guard cell initials (fig. 22, 25, 27–29). The stomata of the abaxial surface are restricted to these areas. Stomata also appear in small isolated groups, near the midvein on the adaxial surface. Another feature of epidermal differentiation is the enlargement of the marginal initials, to which reference has been made earlier.

The subepidermal cells of the lamina elongate also and at maturity are many times their original length, except in the regions immediately beneath the stomatiferous strips where they elongate only slightly (fig. 22, 23).

Most of the internal cells of the laminar portion become chlorenchymatous; however, certain of them elongate and ultimately become fibers (fig. 22, 23, 25). Also a lateral resin canal is differentiated vertically in each half of the young leaf about 125 μ from the margin (fig. 18). These lateral resin canals differentiate basipetally as the leaf is elongated by the basal meristem. They also differentiate acropetally to a certain extent. The presence of three resin canals in each leaf of *Cunninghamia* is distinctive (Plate I, fig. 2) because in *Taxodium* and *Cryptomeria* there is only one. The photosynthetic cells enlarge greatly, but do not keep pace with the vertical growth of the epidermal and subepidermal layers. Therefore, they are placed under stress and soon are stretched until air spaces are formed at their corners (fig. 23). Ultimately the photosynthetic cells separate into transverse anastomosing plates of much the same type as described for *Taxodium* and *Cryptomeria* (fig. 22, 25).

It has been emphasized that differentiation in the laminar portions, starting near the tips of young leaves, proceeds in a basipetal direction. The basal portion of the leaf is meristematic and remains so until the organ is completely mature. Figures 22 to 24 illustrate differentiation in the distal, middle, and

proximal portions of a lamina $3\frac{1}{2}$ mm. in height, as seen in longitudinal section.

Maturation.—The apex of the leaf matures first. The walls of the epidermal cells thicken and become cutinized. The elongated subapical cells are stiffened by the thickening of cell walls (fig. 19), and when the leaf has attained a height of 1 mm. or even less, the tip is already stiff and sharp.

The apical initials are the last cells of the apex to mature (fig. 19). Ultimately one of them usually divides by the insertion of an oblique wall, and the outer derivative elongates forming a stiff hair filled with densely-staining spherical bodies. Similar stiff hairs are formed from many of the marginal initials, as is mentioned earlier. Figure 32, drawn from a section cut parallel with the surface of a leaf, represents a protruding, marginal initial which is undergoing an oblique division. The outer derivative forms an elongated, pointed, stiff hair, and the inner derivative becomes a basal cell as is represented in figure 33. The hairs are formed successively in a basipetal direction. They appear as minute serrations on the margins of the mature leaf.

The stomatiferous strips mature in an interesting manner. In the younger portions of a leaf the cells in these areas are similar in size and structural features (fig. 23, 27), but in the older distal regions there are rows of guard cells separated by epidermal cells which are considerably altered in size and shape (fig. 29). For a study of stomatal development it proved advantageous to use sections cut parallel with the surface of a leaf. The stomata are arranged in parallel rows, and it was easy to follow a row from a region of greater maturity to one of relative immaturity. Figures 27 to 30 illustrate various stages in the development of stomata. The guard cells are oriented with their long axes parallel with the longitudinal axis of the leaf. Each pair of guard cells is usually separated from its neighboring guard cells in the same row by two other epidermal cells. Mitoses which produce this situation are represented in figures 26 and 27. A later stage, with guard cells formed but not enlarged, is represented in figure 28. Figure 29 represents a portion of the epidermis with various ages of guard cells, some of them beginning to separate. A mature stoma is portrayed in figure 30. As the epidermis matures, the cells which separate the stomata in the various rows protrude above the surface of the leaf, apparently squeezed out of position by the elongation of the guard cells (fig. 25, 26). At

maturity the guard cells are sunken and covered partially by surrounding epidermal cells (fig. 31).

The subepidermal cells, with the exception of those beneath the stomatal areas, develop into enormously elongated, thick-walled fibers. Some of these fibers from macerated material exceeded 3 mm. in length.

The maturation of the mesophyll is essentially as described for *Taxodium* and need not be redescribed here. The elongated cells scattered in the mesophyll, often occurring in groups of from two to seven, mature into thick-walled fibers. The abundance of mechanical tissue found in the leaf of *Cunninghamia* results in a very tough and stiff photosynthetic organ, much in contrast to the soft, flexible leaves of *Taxodium* where mechanical tissue is lacking or poorly developed.

The lateral resin canals mature simultaneously with the chlorenchyma. In structure they are similar to the median one, though somewhat smaller (Plate I, fig. 2). As the basal portion of the leaf loses its meristematic character, the lateral resin canals differentiate basipetally through this region, and, when the leaf is completely mature, they may be observed in the cortex of the shoot axis. However, in contrast with the median canal, they end blindly and do not anastomose with other canals. At least no evidence of anastomosing was observed during the present study.

GENERAL ANATOMY OF THE MATURE FOLIAGE LEAF.—Bertrand (1874) published an illustration and a brief description of the anatomy of the mature leaf of *Cunninghamia*. Later Mahlert (1885) and, more recently, Feustel (1921) have contributed very brief accounts without illustrations.

In transection the distal half of the mature leaf resembles an elongated, distorted ellipse (Plate I, fig. 1). The proximal half is often compressed radially, and appears somewhat scale-like (Plate I, fig. 2). The walls of the epidermal cells, especially the outer surfaces, are greatly thickened with a material which stains red with safranin. Pits are very conspicuous especially in the epidermal cells near the margins of the leaf. The stomata are arranged in parallel rows on the abaxial surface, and occur infrequently in scattered areas on the adaxial surface. The guard cells are parallel with the longitudinal axis of the leaf. They are sunken and have heavily-thickened walls (Plate I, fig. 3).

There is a conspicuous hypodermal sheath consisting of cells with walls so thickened that the lumina are often represented by slits or points (Plate I, fig. 6). A similar hypodermal layer has been reported for *Cryptomeria* (Cross, 1941). The walls of the hypodermal cells do not stain with safranin but absorb fast green. The hypodermal layer generally consists of one layer of cells, but it is double in the margins and occasionally it may be double locally elsewhere. The thickened cells are not found in the vicinity of stomata.

The mesophyll consists of well-developed palisade and spongy tissue (Plate I, fig. 1, 5, 6), and the cells have thick walls with simple pits. The palisade con-

sists of two or more layers near the margins; consequently, the leaf is thicker in these regions (Plate I, fig. 1). Many of the cells of the spongy mesophyll are elongated transversely (laterally). Very long, thick-walled fibers are irregularly distributed throughout the mesophyll, occurring either singly or in groups of from two to seven. The fibers are structurally very similar to the fibers of the hypodermal layer. Lateral resin canals are found in the mesophyll of the proximal portions of the leaf, but these are not usually present in sections from the distal half (compare figures 1 and 2 in Plate I). In transection the palisade and spongy tissues are continuous past the vascular bundle as in *Cryptomeria*.

The vascular bundle is large and well developed (Plate I, fig. 6). The cells of the xylem occur in rows, and apparently all of the elements are secondary in origin. With respect to wall thickenings various types of spiral depositions were noticed in the first-formed elements, and some cells with thickenings partially spiral and partially annular were observed. The cells of the later-formed xylem have bordered pits on their radial walls. The xylem is limited toward the adaxial surface by a zone of very thin-walled cells. The cells of this zone are very delicate, and because of technical difficulties usually appeared somewhat crushed in the preparations.

The cells of the functional phloem, like the xylem, are also arranged in rows and are probably secondary in origin. The first-formed phloem, possibly primary phloem, may be located as a zone of crushed cells in Plate I, figure 6. Immediately adjacent to the phloem toward the abaxial surface is the large median resin canal consisting of a cylinder of secretory elements enclosed by a sheath of slightly thickened cells.

Strands of transfusion tissue with well-developed, bordered pits flank the xylem and phloem. The entire bundle is surrounded by a sheath of cells which resemble those of the mesophyll with respect to shape but which have conspicuously thickened walls. This "bundle sheath" varies in thickness from one to several layers (Plate I, fig. 3, 4).

DISCUSSION.—The surface layer at the summit and upper shoulders of the apical meristem of *Cunninghamia* consists of cells which divide both anticlinally and periclinally. However, on the lower shoulders and flanks a discrete surface layer or protoderm is differentiated. Thus, with respect to the surface layer, the shoot apex of *Cunninghamia* seems to represent a condition phylogenetically intermediate between the apices of the Abietaceae and those of *Taxodium* and *Cryptomeria*. The evidence indicates that an entirely discrete surface layer may be evolving in the apical meristem of the Taxodiaceae as a result of a gradual diminution and ultimate loss of periclinial divisions in the outer cells of the shoot apex. The loss of periclinial divisions apparently occurs first in the sides of the shoot apex (*Cunninghamia*), then proceeds acropetally into the flanks or shoulders (deciduous shoots of *Taxodium* and shoots of *Cryptomeria*), and finally reaches the cells of the summit

(permanent shoots of *Taxodium*). The entirely discrete surface layer at the shoot apex of the permanent shoots of *Taxodium* may be regarded as a tunica (Cross, 1939), a protoderm (Strasburger, 1872) or a dermatogen. Perhaps it should be suggested at this time that the entire apex of the permanent shoot of *Taxodium* (Cross, 1939; Pl. 9, fig. 3), with its uniseriate tunica and clearly differentiated subterminal regions or zones, resembles definitely the shoot apex of *Opuntia cylindrica* (Boke, 1941; fig. 2). The differences appear to be quantitative rather than qualitative, and, if additional researches prove this to be the case, it should be possible to correlate at least some of the apparently divergent "types" of cellular

patterns found in the shoot apices of coniferous and angiospermous genera.

The subapical mother cells in the shoot apex of *Cunninghamia* are perhaps more clearly defined than in any other investigated coniferous genus. They are equivalent in origin, position, function, and some structural features to the "subterminal mother cells" in the shoot apices of seedlings of *Cycas revoluta* (Foster, 1939). As a matter of fact, the entire shoot apex of *Cunninghamia* is structurally and functionally suggestive of that described for the seedlings of *Cycas*, if one disregards differences in size and the presence of a protoderm on the flanks of the apex of *Cunninghamia*. Foster (1939) has pointed out that

with respect to shoot apices "probably the closest resemblance to *Cycas* is shown by certain of the Abietineae." However, using the shoot of *Abies venusta* as an example, Foster emphasizes that there are significant differences, particularly with respect to cellular size and arrangement. Specifically, the cells of the peripheral tissue in *Abies* are more stratified, and the peripheral tissue is, therefore, more rigidly delimited from the central tissue (pith mother cells) than in *Cycas*. Because of these differences Foster is inclined to question the equivalence of the various zones in the shoot apices of *Abies* and *Cycas*. If similar comparisons are made using *Cycas* and *Cunninghamia*, it is apparent at once that the points of contrast listed by Foster are much less marked. A comparison of Foster's figures of *Cycas* with those of *Cunninghamia* will show that differences in cellular size may be discounted, and that the two growth zones (peripheral and central tissues) are not always more clearly delimited in *Cunninghamia* than in *Cycas*.

I should like to suggest also that the use of structural features such as "cellular size," "degree of stratification," etc., in determining the equivalence of growth zones should be used with caution, because considerable variation with respect to these characteristics is generally known to exist in the apices of related genera, and even in apices of species belonging to the same genus. It seems likely that characteristics such as origin, position, and function may constitute reasonably reliable criteria for establishing the equivalence of growth zones in the shoot apices of the various genera of vascular plants, and from this point of view the similarities of *Cunninghamia* and *Cycas* appear to be noteworthy.

Thus, apparently there is some possibility that the shoot apices of the various genera of Taxodiaceae (particularly *Cunninghamia* and *Taxodium*) may serve to articulate the uniquely zoned apices of the cycads with those of certain angiosperms, and a tentative "series" (not phylogenetic) consisting of *Cycas*, *Cunninghamia*, *Taxodium*, and *Opuntia*, arranged in the order of their similarities, might provide a basis for additional inquiry. However, it must be emphasized that much work remains to be done be-

fore the relationships, if any, can be elucidated with confidence.

SUMMARY

The apical meristem and the ontogeny of the foliage leaf of *Cunninghamia* are described. Strasburger's (1872) concept of the shoot apex, i.e., that it consists of a protoderm, periblem, and plerome, is not supported, since no indication of these histogens was found in any of forty-five apices. On the contrary the apex appears to consist of five poorly delimited growth zones. There is a single tier of apical initials (zone 1) which occupies the summit and upper shoulders. Lateral derivatives of the apical initials produce a protoderm (zone 2) in which anticlinal divisions predominate. Basal derivatives of the apical initials become the subapical mother cells (zone 3). Derivatives of the subapical mother cells give rise to the peripheral, or flanking, meristem (zone 4) and to the pith mother cells (zone 5). The peripheral tissue produces the cortex and probably most of the vascular tissue. It is concluded that the shoot apex of *Cunninghamia* is less specialized and, therefore, probably more primitive than are those of *Taxodium* and *Cryptomeria*. It is similar structurally to the shoot apex described for seedlings of *Cycas revoluta* (Foster, 1939).

The origin and development of the foliage leaf are essentially as described for *Taxodium* and *Cryptomeria*. Neither an adaxial meristem nor a plate meristem is developed, a fact which may be correlated with the restricted radial and lateral dimensions of the mature leaf. A basal rib meristem is formed early in ontogeny, and the derivatives produce most of the internal tissue of the leaf. The resin canals of *Cunninghamia* present contrasting features in that each leaf has two lateral and one median canal, whereas leaves of *Taxodium* and *Cryptomeria* have a single canal each. Further, the median canal in the leaf of *Cunninghamia* anastomoses with canals from other leaves in the cortex of the shoot axis, although this is not true of the lateral ones.

THE CHROMOSOMES AND NUCLEOLI OF MEDEOLA VIRGINIANA¹

Robert N. Stewart and Ronald Bamford

MANY OF the members of the genera *Trillium* and *Paris* have been the subject of much valuable cytological research. It seemed probable, therefore, that *Medeola*, a closely related genus, might also furnish favorable material for similar studies. This paper is a report of the observations of the chromosomes and nucleoli of *Medeola virginiana*, the only species of the genus. As far as the authors are aware no previous reports of the chromosomes of this species have been made.

The flower buds were collected late in June from about fifty scattered plants growing in the vicinity of College Park, Maryland, and this material was preserved in a 3:1 absolute alcohol-acetic acid mixture. Preparations were made from this preserved material and from fresh material by the use of McCallum's Iron-propionocarmine (Johansen, 1940).

When observations were made of the metaphase and anaphase stages of mitosis in the young ovary wall, fourteen chromosomes were present (fig. 1 and 2). Similar observations were made of metaphase I of meiosis (fig. 6) and the metaphase of the first microspore division (fig. 10). The presence of seven chromosomes in both of these stages confirmed the diploid counts. Some tapetal cells were located which had twenty-eight chromosomes and were, therefore, tetraploid.

Like the chromosomes of both *Trillium* and *Paris*, those of *Medeola* are large, and, since the kinetochores are plainly visible, it was possible to measure accurately the length of the arms as well as the length of the whole chromosomes. In this way each chromosome could be easily identified and a ratio established (Woods and Bamford, 1937) for it. The seven chromosomes, arranged in order of total length, were then arbitrarily designated (fig. 12) as follows:

Chromosome A, ratio 1.10	Chromosome D, ratio 3.06
Chromosome B, ratio 1.42	Chromosome E, ratio 9.11
Chromosome C, ratio 2.22	Chromosome F, ratio 1.14
Chromosome G, ratio 1.72 (secondary constriction, short arm)	

The most interesting part of these observations was the nucleolar-chromosome relationship which could be followed closely. In the early telophase of mitosis two small nucleoli were observed attached to the G chromosomes. Later in this same stage and during the following resting stages the nucleoli were present, but their chromosome attachments could not

be observed. Apparently some fusion takes place because certain cells contain one large nucleolus and others two smaller ones. In the very late prophase of mitosis one pair of chromosomes (G) could be seen attached to one (fig. 5) or two nucleoli at their secondary constriction. In the case of the tetraploid cell of the tapetum in a late prophase or early metaphase, four nucleoli could occasionally be observed and each was connected to one G chromosome (fig. 3). During the late diakinesis stage of meiosis the bivalent G chromosome was frequently observed with the one nucleolus attached to it (fig. 4). The interphase between the two meiotic divisions is quite marked and nucleoli are formed. During prophase II two nucleoli could be observed, and one was attached to each of the two chromatids (fig. 11) of chromosome G. At a later stage of this same division, late anaphase or early telophase, a similar observation could be made. Here a single nucleolus is attached to the G chromosome (fig. 7). During the prophase of the first microspore division a nucleolus was again observed (fig. 13) attached to chromosomes G. In all the above cases the nucleolus was located at the secondary constriction on the short arm (fig. 5) of this chromosome.

In the mid-prophase of the first division of meiosis we have been unable to recognize the individual chromosomes but in such preparations only, the "nucleolar-organizing body" is clearly visible (fig. 8 and 9), attached to a single nucleolus in each case.

The chromosome morphology of both *Trillium* and *Paris* has been described by Gotoh (1933), Haga (1934), Warmke (1937), Matsuura (1938), Darlington (1941), and many others. The five chromosomes in the haploid complement of the diploid species in these two genera appear identical except for the presence of a satellite or secondary constriction chromosome D in *Paris* (Haga, 1934; Matsuura, 1938; Darlington, 1941). Chromosomes A, B, C, and E of *Trillium* and *Paris* are apparently like chromosomes A, C, D, and F in the present species. Chromosome D of *Trillium* is not comparable to any chromosome in *Paris* but is like chromosome E in *Medeola*. Also chromosome D of *Paris* is not comparable to any chromosome in *Trillium* but is like chromosome G of *Medeola*. These are the nucleolar chromosomes in both *Paris* (Matsuura, 1938) and *Medeola*, and have a secondary constriction in the short arms. Chromosome B of *Medeola*, or a like chromosome, is absent in *Paris* and *Trillium*. The

similarity in chromosome complements of these three genera is interesting in view of their generally accepted close relationship from a taxonomic standpoint, but at the same time the differences in both

morphology and number of the chromosomes indicate that they are separate and distinct forms.

The question of the chromosome-nucleolus relationship has been surveyed recently by many au-

thors, particularly by Gates (1937, 1939), his students (Nandi, 1937; Bhatia, 1938; Iyengar, 1939; Mensinkai, 1939; Jacob, 1940; Sikka, 1940; Pathak, 1940; Bhaduri, 1941), and many others (Fernandes, 1935; Woods, 1937; Resende, 1937, 1939; Sato, 1938, 1939; Matsuura, 1938). It seems unnecessary to discuss it in detail here again. The majority of these recent investigations have tended to strengthen the basic idea of Heitz (1931). As Warmke (1941) has recently pointed out, there is "a definite and constant relationship between secondary constrictions, including satellite constrictions, and the formation of nucleoli." Resende (1937) made an extensive survey of many species and varieties of the higher plants and concluded that there is a SAT-region—the satellite or secondary constriction thread—in at least one chromosome of the complement in all plants, and that the nucleolus is formed on that constriction thread. In some species of *Trillium* he was unable to find this but suggested that it was due to the extremely small size.

One of the most questionable phases of the nucleolus and chromosome association is the exact point of nucleolar organization and whether the constriction thread organizes the nucleolus or the organization of the nucleolus results in the constriction thread. Many workers, Heitz (1931) and Resende (1937) among them, have concluded from observation alone that the nucleolus is organized on or by the constriction thread. McClintock (1934), on the

basis of various experimental evidence, demonstrated clearly that the nucleoli in *Zea* are formed by a definite heterochromatic region which she called the nucleolar-organizing body, and that the constriction thread was a result of nucleolar formation.

Matsuura (1938) was unable to find satellite or secondary constrictions in *Trillium kamschaticum* and reported that the nucleoli were organized at the end of the short arm of chromosome E and at both ends of chromosome A. He designated the nucleolar chromosomes of the type he found in *Paris* as the interstitial type and the *Trillium* chromosomes as the terminal type. He further stated that he could find no heterochromatic body similar to the nucleolar-organizing body of *Zea* in either *Paris* or *Trillium*.

In *Medeola* a large heterochromatic region similar to the nucleolar-organizer in *Zea* is always seen associated with the nucleolus in mid-prophase of meiosis, although it is hidden by the euchromatin in all the more condensed stages. McClintock showed that neither the relative size of the organizers within a cell nor the relative size between different strains was important. Therefore, it seems possible that nucleolar-organizers may vary in size, even between closely related forms, and those in *Paris* and *Trillium* may be very small.

SECONDARY SPORES IN THE MYCELIUM OF THE CULTIVATED MUSHROOM, *PSALLIOTA CAMPESTRIS* FR.¹

Albert M. Kligman

THE WRITER has had occasion, in connection with the commercial manufacture of spawn, to keep on hand a number of cultures of the cultivated mushroom, *Psalliota campestris*. Many of these cultures were transferred only at intervals of about six months. Following the transfer of old agar tube cultures, mycelia have occasionally been observed arising near the bottom of the slant independent of the piece of inoculum and having no observable connection with it. When transfers were made to Petri dishes from old agar tube cultures, mycelia occasionally arose which were distinctly separate from the piece of inoculum. This same phenomenon has also been observed by Dr. J. W. Sinden of the Pennsylvania State College, who has worked extensively with cultures of this organism. On the other hand, transfers made from relatively young cultures of *P. campestris* have never been accompanied by the development of mycelium in any region except that in direct contact with the inoculum.

On the basis of these observations, covering a period of about two years, it seemed clear that hyphal elements of some kind, which were being produced in old cultures, became detached during the transfer and unexpectedly initiated mycelia. To the writer's knowledge, no hyphal structures of the character and behavior mentioned above have been previously described in the mycelium of *P. campestris* (Colson, 1935; Hein, 1930; Sass, 1928). These observations led to further detailed studies on the mycelia of old cultures of this organism. A large number of old cultures on potato-dextrose and malt agars have been examined. Hyphal elements which resemble chlamydospores have been consistently observed in cultures of more than three months' duration. Chlamydospore-like cells have not been observed in young cultures of *P. campestris*. It seems likely that they have not been previously described, because old cultures were probably not studied in detail.

CHLAMYDOSPORE-LIKE CELLS IN VARIETIES OF *P. CAMPESTRIS*.—Chlamydospore-like bodies were first observed in the mycelia of the variety known as "snow-white." This variety is the one now almost exclusively cultivated in the eastern United States. In previous years other varieties of mushrooms distinctly different from the "snow-white" have been cultivated. They have all been considered varieties or forms of the cultivated mushroom, but occasionally attempts have been made to give them specific status. They include a great diversity of forms, ranging from those having a thick stem with a darkbrown, scaly cap to those which are light-cream, thin-stemmed,

and without floccose scales on the pileus. In the trade these varieties are familiarly known as the "big brown" and the "cream." Old cultures of the brown and cream varieties may form chlamydospore-like bodies as freely as the snow-white. Therefore, most of this study was carried out with the snow-white, since it appears to be representative of the species.

The occurrence of chlamydospore-like elements in the cultivated two-spored varieties of *P. campestris* affords an opportunity to examine further their relationship to the wild four-spored variety. Miss Colson (1935) has shown that, in general, the mycelial features of the wild variety correspond to those of the cultivated types. The quadrisporous wild variety differs from the bisporous cultivated one in habitat, distribution, and physiological behavior. No one has succeeded, so far as the writer is aware, in growing the wild variety in beds of composted manure. The distinction between these two forms is further emphasized by the fact that none of the chlamydospore-like bodies was observed in old cultures of the wild type. Owing to the conspicuous formation of chlamydospore-like bodies, the mature mycelium of the cultivated form presents an altogether different aspect from that of the wild type. This distinction further establishes the independent status of the two forms, a point which is frequently overlooked, particularly in popular works.

CHLAMYDOSPORE-LIKE CELLS IN THE MYCELIA OF FERTILE RACES.—The snow-white strain of *P. campestris* comprises an indeterminate number of races differing in rate of growth, ability to sector, cultural appearance, productivity, etc. Commercial spawn makers propagate desirable races from basidiospores or by culturing a piece of tissue from the sporophore. Cultures obtained by either of these methods are generally fertile, that is, they are capable of producing mushrooms. Studies of many fertile races showed that all of them produced chlamydospore-like cells in old cultures, and, as a matter of fact, microscopically they were all very similar.

The cells of the young hyphae, which are rather long and narrow and anastomose freely, are organized into highly branched filaments. Under the low-power objective it is difficult to distinguish the septum between adjoining cells. In old hyphae, on the other hand, the cells are very much enlarged transversely and considerably reduced in length. The hyphae appear to be fragmented into series of conspicuous chain-like cells. As a result of the thickening and rounding off of the end walls, the cells assume an individual character and can easily be seen under the low-power objective. The size and disposition of such cells, which are here regarded as secondary spores, readily distinguish them from the narrow, elongated cells of the young mycelium. For the sake of convenience, these cells which are uneven in size and

¹ Received for publication December 18, 1941.

The writer wishes to express his indebtedness to Dr. H. H. York of the University of Pennsylvania and Dr. J. W. Sinden of the Pennsylvania State College for their aid in the course of the work and in the preparation of the manuscript.

shape may be called chlamydospores. Unfortunately, the term chlamydospore has been rather loosely used. Clearly they are not oidia as Brefeld (1877) and Brodie (1936) used the term. Biggs (1937) has illustrated swollen and bulbil-like cells in the mycelium of *Corticium coronilla* which are rather thick walled and which, in her opinion, resemble chlamydospores more than conidia. These cells are somewhat similar to those described in this study in the mycelium of *P. campestris*. In this discussion, chlamydospores are regarded simply as transformed vegetative cells which are capable of giving rise to new mycelia.

Ordinarily, young cells are rarely more than $4\ \mu$ in diameter and may attain a length of $45\ \mu$ or more. The chlamydospores, on the other hand, were rarely less than $8\ \mu$ in diameter, and rarely exceeded $25\ \mu$ in length. An average chlamydospore is about $10\ \mu$ by $14\ \mu$. Reduction in the length of each cell is accomplished by means of septa which partition the young cells as they mature. The chlamydospores are ovoid, globose, rectangular, elliptical, and show eccentric modifications of these shapes. The swelling of the cells as they mature presumably indicates an accumulation of food materials. This is evidenced by the fact that the cytoplasm of chlamydospores appears to be loaded with granular material and is much denser than the cytoplasm of young cells. Not all the cells in an old mycelium enlarge in this fashion, so that occasionally a long narrow cell appears in a chain of chlamydospores. The cells deep down in the agar medium were never observed to be converted into chlamydospores. As a result of random septation and enlargement, chlamydospores may be terminal, intercalary or, as is more frequently the case, in long chains. Some of the spores showed a very conspicuous thickening of the walls and appeared to be easily separable from contiguous cells. Most of the chlamydospores developed in hyphae which were imbedded in the uppermost part of the agar medium. Segmentation of the hyphae into clearly dissociable units did not occur to the extent that the chlamydospores were deciduous of their own accord as, for instance, is the case with secondary spores of species of *Mucor*, *Saprolegnia*, *Coprinus*, etc. In a great many cases the cell walls were not conspicuously thickened and the cells in a chain did not appear to be readily separable. All stages in the formation of chlamydospores were observed (fig. 7 and 8). Frequently swollen cells which were to undergo septation showed a pinching or constricting, so that they appeared somewhat peanut-shaped. Hein (1930) noted large irregular cells in the mycelial strands of *P. campestris*. These have nothing in common with chlamydospores. They are thin-walled, do not contain a dense cytoplasm and frequently have their end walls dissolved to form long tubes. In addition, they occur only in the mycelial strand in which they apparently serve as conducting elements.

Chlamydospores have a pronounced avidity for the stains used in studying them. Cotton blue, safranin, and haematoxylin bring them out clearly. Occasionally groups of cells appear which do not take the

stains at all and which are apparently devoid of protoplasmic contents (fig. 5). Ordinarily chlamydospores contain large quantities of granules of different sizes and shapes dispersed unevenly throughout the cytoplasm.

Cell types in a fertile race. $\times 400$.—Fig. 9. Single cells of a fertile race separated by crushing on a glass slide. $\times 450$.

For making temporary mounts, agar blocks containing the mycelium were stained in aqueous safranin and cotton blue and crushed under a cover glass in lacto-phenol. In safranin mounts of young mycelia, hemispherical pads were occasionally observed on both sides of a septum. These pads have been noted by previous investigators of this species and other Hymenomycetes (Colson, 1935; Hein, 1930; Sass, 1928). However, in cells which are being converted into chlamydospores and which have their end walls rounded off, such pads were never ob-

served. Presumably, these pads in young cells are connected by a thin strand of protoplasm which passes through a pore in the septum. The fact that they were not observed in the chlamydospores further emphasizes the independent character of such cells.

In studying the nuclei it was not necessary to employ the paraffin microtome technique. Thin agar slices were fixed and stained in Heidenhain's haematoxylin. After destaining the slices were mounted in glycerin jelly and crushed under a cover glass. This type of mount gave a better idea of the three dimensional character of the mycelium.

Chlamydospores are multinucleate and generally contain three to six nuclei irregularly disposed. Cells of the young mycelium are also multinucleate but as a rule contain more than six nuclei in a cell (Colson, 1935; Hirmer, 1920; Sass, 1928). The larger chlamydospores sometimes contained more than six nuclei. The nuclei were not disposed in pairs as in the secondary mycelia of many Hymenomycetes. Infrequently a cell was observed which seemed to have only one or two nuclei, but imperfections in the staining process and the extremely small size of the nuclei prejudiced the reliability of such counts. Dividing nuclei were not observed in mature cells. In the Hymenomycetes, so far as known, nuclear divisions generally occur in the tip cells of the hyphae, where growth is taking place. Hirmer (1920) has shown that this is also true for *Psalliotia campestris*, and the writer has confirmed this by staining mycelia grown on glass slides. Chlamydospores contained, as pointed out above, three to six nuclei, whereas younger cells contained more nuclei. The reduction in the number of nuclei in old cells may be explained by the fact that septa subsequently form which partition the mother cell into two or three daughter cells. Older cells are, of course, much shorter in length as a result of this partitioning. Hirmer (1920) noted that cells of the hyphae in older cultures of *Psalliotia perrara* contained fewer nuclei than cells of young cultures. Since he observed that nuclear behavior in *P. perrara* corresponds closely to that in *P. campestris*, it seems evident that septation is responsible in both of these species for the reduced number of nuclei in old cells. This type of behavior is not at all frequent in the Hymenomycetes. Usually a dikaryotic mycelium, for instance, which contains two nuclei in every cell, suffers no further changes in the nuclear content of each cell as the mycelium ages. In most Hymenomycetes the distribution of daughter nuclei in the tip cells is associated with the formation of a septum, so that the daughter nuclei are allocated evenly to the two cells which result (Buller, 1941). Thus, septum formation is always associated with nuclear division in the tip cells. In this case, however, the formation of septa which occurs in older cells as a process independent of cell formation, appears at the tip to be not at all associated with nuclear division.

It has been argued that chlamydospore formation is purely a laboratory phenomenon which does not

occur under field conditions. In many species it seems to be associated with the drying up and staling of the medium. In *P. campestris* there is no evidence that chlamydospores occur anywhere other than in old agar cultures. Attempts to find them in mycelia grown on manure and rye grains have been unsuccessful, even after the cultures were exposed to low temperatures for months. At any rate, the fact that chlamydospores develop in old cultures of *P. campestris* emphasizes further the latent possibilities inherent in a mycelium for acquiring new growth habits under special environmental conditions.

The formation of chlamydospores is most abundant at and just below the surface of the agar. The aerial part of the mycelium is apparently not converted into chlamydospores. The mycelium next to the inoculum piece produces the greatest number of chlamydospores, since it is the oldest part of the culture. For the most part chlamydospores are imbedded in the agar and are not free for dissemination, as is the case with most secondary spores. The appearance of errant mycelia when cultures were transferred is attributed to the dislodging of chlamydospores lying at the surface of the medium. Since for the most part they tend to remain in place, the phenomenon is only occasional. As will be described later they can be separated by mechanical means, though it must be emphasized that normally they do not appear to be deciduous of their own accord. Apparently nutrient deficiency encourages their formation. In cultures grown on potato extract without dextrose they begin to form earlier and are more abundant.

OCCURRENCE OF SECONDARY SPORES IN STERILE RACES.—As a rule monosporous cultures are fertile (Lambert, 1938). Sinden (1937) has pointed out, however, that cultures from single basidiospores are sometimes sterile, that is, spawn made from such cultures is not capable of producing sporophores. The mycelia of sterile races derived from single spores show a great many variations from the normal fertile types. As a matter of fact, every manner of physiological and morphological variation can be discovered in sterile races. A description of these variations is not pertinent here. Sterile races are included in this discussion because it is precisely in some of these that chlamydospore production is most pronounced. Moreover, chlamydospore production in some of these races is not a result of the aging of the culture but seems to be a function of growing mycelium.

Fifteen sterile races have been studied.² Some of these are so divergent from the normal type that they could never be identified as *P. campestris* if their origin were not known. In four races chlamydospores were produced in great abundance and with striking regularity in shape. In these the youngest hyphae show frequent swellings and constrictions in preparation for spore formation. Only the mycelia of these four races will be described. The spherical cells figured by Biggs (1937) in her group IV isolates of

² Seven of these races were obtained from J. W. Sinden of the Pennsylvania State College.

Corticium coronilla are very similar to those which occur in these sterile races of *P. campestris*.

In the fertile races, chlamydospores are formed by the production of septa which partition young cells. The resultant cells swell up, round off at the margins, and become chlamydospores. In the sterile races, on the other hand, spores are not cut out by septa formation. Young hyphae swell up in such a way that in outline they are very undulating. Swollen regions alternate in a regular series with regions of much lesser diameter. Ultimately, as a result of the continued swelling, the sides of the hyphae where no swelling occurs are brought into contact and spores are pinched off. It is possible that a process of constriction also aids in pinching off spores in this manner. The spores which result are consistently rounder and more uniform than those produced in fertile races (fig. 2 and 6). In contrast to this method cells can frequently be observed which are giving rise to buds. Buds may apparently arise anywhere along the periphery of a wall, and so may be terminal, lateral, or eccentric. Large and small cells alike may give rise to one or more buds which are finally separated from the mother cell by closure of the walls. In old cultures practically the entire mycelium is converted into chlamydospores. Generally the secondary spores of the sterile races are not as thick walled as are those which occur in fertile strains.

In stained mounts the cytoplasm appears very smooth and finely granular. No large granules or conspicuous inclusions occur nor does the cytoplasm appear to be as dense as in the fertile races. In studying nuclei great difficulty was encountered in getting them to stain properly. In general two to four nuclei were observed in each cell. Larger cells were observed in which as many as seven nuclei were counted. Very small spores, which are not infrequent in the four sterile races under discussion, often appeared to be uninucleated. The trapping of nuclei in spores follows the same general pattern as in the fertile strains. Young cells contain many more nuclei than older cells which have been cut out as chlamydospores. It is of interest to note that these strains which are so divergent from the normal fertile types are a cogent proof of the amount of novelty which can be secured with single spore isolations.

ISOLATION OF SINGLE CHLAMYDOSPORES IN FERTILE RACES.—The existence of chlamydospores in the mycelium of *P. campestris* offers an opportunity to examine their sexual and genetical nature. The mycelium of *P. campestris* does not exhibit clamp connections nor are the cells binucleate as is the case in the secondary mycelium of most of the Hymenomycetes (Buller, 1941). Ordinarily the basidiospores of *P. campestris* are initially bi-nucleate and single basidiospores give rise to a bisexual mycelium which is fertile. In the multinucleated cells of the mycelium the nuclei do not seem to be disposed in pairs so that there are no evident forces operating to hold nuclei of opposite sex together (Colson, 1935; Hirmer, 1920; Sass, 1928). The disposition of nuclei in pairs first becomes evident in the subhymenium, where it

is possible to observe as many as three pairs of nuclei in one cell. In view of the fact that chlamydospores are cut out by a process of random septation, it certainly seems possible that a chlamydospore might be produced which contained nuclei of only one sex. Unisexual spores are sometimes produced on a bisexual mycelium in certain Ascomycetes and Hymenomycetes. The conidia produced on the bisexual mycelium of *Neurospora tetrasperma* are frequently unisexual (Dodge, 1928). A unisexual conidium may contain more than one nucleus provided the nuclei are all of the same sex. This phenomenon happens as a result of random trapping of nuclei during spore formation. In *Collybia velutipes* the oidia produced on the bisexual secondary mycelium are regularly uni-nucleated (Brodie, 1936). In this way unisexual oidia are produced on a bisexual mycelium. The following experiment was designed to determine whether this phenomenon, which has been called deploidization by Buller (1941), may occur in the mycelium of *P. campestris* when chlamydospores develop.

Since chlamydospores are imbedded in the agar, special techniques must be employed to make single spore isolations. Considerable difficulty was encountered because the cells tended to stick together in groups. Agar blocks containing the spores were put into two per cent dextrose solution for two days and then crushed between glass slides. The soft mass was then washed off into a test tube by means of a pipette. The tube was agitated vigorously and the contents sprayed over the surface of a series of Petri dishes containing potato-dextrose agar. Microscopic examination showed that in a few instances single chlamydospores had been separated by the treatment. A week later spores which showed signs of developing were picked off with a needle. Twelve single-spore cultures were finally obtained.

No cytological or morphological differences could be observed in these twelve cultures. In each case the typical multinucleated mycelium of *P. campestris* appeared. The parent culture was a single basidiospore race, and thus had genetic status. Twelve bottles of rye spawn were made from the twelve cultures. One bottle of spawn was used to plant forty-five square feet of bed space in a commercial mushroom house so that in all 540 square feet were spawned. Mushrooms began to appear on all twelve plots in about six weeks. The number of pound baskets picked from each plot was recorded. The plots were kept in bearing for three months. The approximate yield of each plot fell rather close to one and a half pounds per square foot. It was evident that there were not significant variations of any character in any of the twelve samples. It seemed that no dissociations from the parent culture had occurred as a result of a single cell isolations. Apparently any cell in the culture is endowed with capacities which identify it with all other cells in the same mycelium regardless of size, shape, and nuclear content. Since all the cultures were fertile, it may be assumed that each chlamydospore contained at least two nuclei of

opposite sex. If unisexual cells do occur, they are rather infrequent. Even though the nuclei are not disposed in pairs, it seems evident that they are distributed in such a way that each cell receives at least two which are of opposite sex. Perhaps the multinucleate condition may, on the basis of these observations, be considered as a protection against the segregation of nuclei into unisexual spores. It is worth noting that in most genetical studies with single spore cultures, the investigations have very largely been carried out in Petri-dish cultures. In this instance, an opportunity to study hundreds of sporophores under field conditions was afforded. Variations affecting the mushrooms would most certainly have been observed.

SUMMARY

Chlamydospore-like cells have been described in varieties and races of the cultivated mushroom, *Psalliota campestris* Fr.

The brown and white varieties resemble each other in their capacity to produce chlamydospores. The

wild four-spored variety does not exhibit this capacity in agar cultures.

Fertile races produce secondary spores which are very variable in size and shape and which tend to be linear rather than round. The cytoplasm of such spores is dense and loaded with granules. Sterile races produce secondary spores which are uniformly spherical and which do not contain a dense cytoplasm. In addition, the young mycelia of certain sterile races produce chlamydospores in contrast to the fertile races in which chlamydospores are produced only in mature mycelia.

Chlamydospores in sterile and fertile races are multinucleate. Twelve single chlamydospores were isolated from a fertile race and mushrooms were obtained from each of the cultures made from these spores. No variations in any of the twelve cultures have been observed.

INHERITANCE OF SMUT RESISTANCE IN HYBRIDS OF NAVARRO OATS¹

George M. Reed

THE NAVARRO oat variety has exhibited a remarkable resistance to many races of loose and covered smut (Reed, 1940). It has been tested with nineteen races of loose smut (*Ustilago avenae* (Pers.) Jens.) and fourteen of the covered (*U. levis* (Kell. and Sw.) Magn.), and with additional collections of both smuts, most of which probably belong to the races differentiated. No smutted plants of Navarro have been recorded except in one case where one infected plant, possibly a stray of some other variety, was observed.

The first Navarro plant was found in an oat field in Navarro County, Texas, about 1919, nothing definite being known concerning its origin (Stanton, 1933). It may have arisen as a hybrid between a variety of red oats (*Avena byzantina* C. Koch) and the common oat (*A. sativa* L.). Navarro has close affinities with the former collective species and is ordi-

narily classified as a member of the red oat group. It is very distinctive in several characters. It is an early, semi-erect variety and, in the later stages of growth and maturity, has a well defined purplish bloom. The panicles are compact with large, plump, three-grained spikelets. It does not rank high from the standpoint of yield or cold resistance. Further, it is very susceptible to rusts. Its chief agronomic value is due to its smut resistance, and it has been used extensively in oat breeding investigations.

The high degree of resistance of Navarro makes it interesting from the standpoint of the genetics of resistance to smuts. Accordingly, it has been crossed with other varieties, and the reaction of the hybrids to definite races of both loose and covered smuts has been determined. Successful crosses between Navarro and Hull-less, Black Mesdag, and Gothland were made in 1936. The F₁ plants were grown in 1937, the F₂ plants in 1938 and later years, and the F₃ generations in 1939, 1940, and 1941.

¹ Received for publication December 19, 1941.
Brooklyn Botanic Garden Contribution No. 96.

The methods previously described were employed (Reed, 1941). Usually, the inoculated F_2 plants were grown to maturity in the greenhouse, although some were planted in the field. Most of the data on the third generation progenies were obtained in the field, although some families were grown under greenhouse conditions. The seed, inoculated by dusting with dry chlamydospores, was germinated in sand with a moisture content of about 20 per cent of its water-holding capacity and at a temperature of approximately 20°C . The seedlings usually emerged about the fourth day and were ready for transplanting in six to eight days.

The data for the reaction of the parental varieties to the smut races used for inoculation are recorded in table 1 and for the second and third generations of the hybrids in table 2. In the latter table the distribution of the third generation progenies, based upon the percentage of infection, is given. The F_3 generation progenies were inoculated with different races of smuts, the seed of the F_2 plants being divided into sets, each set being inoculated with one of the races.

In the discussion, the third generation progenies are grouped as resistant, segregating, and susceptible. In resistant progenies, no infected plants occur. It is not easy to separate the segregating and susceptible progenies in the hybrids where two or more factors are involved. The classification of segregating progenies as giving less than 50 per cent infection, while the susceptible progenies give more than 50 per cent of infected plants, is fairly satisfactory where a single factor for resistance is concerned. In cases where two or more factors are involved this

same grouping has some convenience in presenting the data.

HYBRID 90. NAVARRO \times HULL-LESS.—Four crosses between Navarro and Hull-less were made, and separate sets of seeds of the second and third generations were inoculated with three races of *Ustilago avenae* and two of *U. levis*. Navarro is resistant to all five of these races, while Hull-less is susceptible to four and resistant to one.

Results with *Ustilago avenae*, Race 1.—In the experiments with this race of smut 241 plants of Hull-less were inoculated, of which 222 (92.1 per cent) were infected, the results in the different experiments ranging from 80.9 to 100 per cent. In contrast, the 241 inoculated plants of Navarro gave no infection.

There were 74 F_2 plants inoculated with race 1 of the loose smut and 7 (9.4 per cent) were infected. These data may indicate that there is a two-factor difference in the inheritance of resistance to this race of smut. On this basis, 6.25 per cent of the F_2 plants should be infected, or 5 out of the 74 inoculated.

The data for the F_3 generation are in harmony with the two-factor explanation, 265 progenies being grown, with the following results:

	Resistant	Segregating	Susceptible
Observed	116	127	22
Expected (7:8:1)	116	132.5	16.5

It is, of course, not at all easy to separate sharply the segregating from the susceptible group. How-

Hybrid 91. Navarro Black Mesdag	L- 7	62	3	4.8	97	23	8	1	0	0	0	0	0	1	0	0	130	33	25.3
	I- 9	—	—	—	130	9	4	0	0	0	2	0	0	0	0	1	146	16	10.9
	A-12	63	3	4.7	81	30	8	4	2	2	1	1	1	0	0	0	130	49	37.6
	A-10	—	—	—	25	0	0	0	0	0	0	0	0	0	0	0	25	0	0
	A- 1	67	5	7.4	78	37	22	13	6	2	1	1	0	3	2	0	165	87	52.7
Hybrid 92. Navarro Gothland	A-10	17	0	0	23	1	0	1	0	0	0	0	0	0	0	0	25	2	8.0

ever, if these two groups are combined, we find that 56.25 per cent of the progenies should contain smutted plants and a percentage of 56.22 was actually obtained in the experiments.

Results with Ustilago levis, Race 1.—In the experiments with this smut 208 plants of Hull-less were inoculated, of which 174 (83.6 per cent) were infected, the percentage varying from 58.3 to 97.2; 226 plants of Navarro were inoculated and none was infected. In the F_2 generation 70 plants were inoculated and 4 (5.7 per cent) were infected. These data may indicate either a two- or three-factor difference, and the results for the third generation are necessary to determine which is the more probable explanation. On the basis of two factors, 6.25 per cent of the F_2 plants should be infected while, on the assumption of three factors, the percentage of infection should be 1.55. There were 265 F_3 progenies grown, with the following results:

	Resistant	Segregating	Susceptible
Observed	148	103	14
Expected (37:26:1)	153	108	4

The distribution of the progenies is in line with the three-factor assumption and quite different from what would be obtained if only two factors for resistance were involved.

Results with Ustilago levis, Race 7.—There were 202 plants of Hull-less inoculated with this race of covered smut and 167 (82.6 per cent) were infected. Usually, the percentage of infection in the different experiments was high; in one test, however, only 45 per cent of the inoculated plants were smutted. In contrast, 338 plants of Navarro were inoculated and none was infected.

There were 132 F_2 plants of the hybrid inoculated and 4 (3 per cent) were infected. These results may indicate that three different factors for resistance are involved, and this assumption implies that, out of a total of 132 plants, 130 should be resistant and 2 (1.55 per cent) infected. In the third generation, 226 progenies were grown, the results secured being as follows:

	Resistant	Segregating	Susceptible
Observed	124	91	11
Expected (37:26:1)	130	92	3

The results secured correspond quite well with those obtained with the F_2 generation and indicate that three distinct factors for resistance are involved. The combined groups of segregating and susceptible constitute 45.1 per cent of the progenies while, according to expectation, 42.17 per cent should be infected.

Results with Ustilago avenae, Race 12.—Hull-less is susceptible to this race of smut, 397 plants being inoculated and 325 (81.8 per cent) infected. Navarro, in contrast, is resistant, no infected plants being found in a total of 506 inoculated.

The results with both the second and third generations of this hybrid, inoculated with this race of smut, are in striking contrast to those obtained with the previous races. A total of 121 F_2 plants was inoculated and 62 (51.2 per cent) were infected. Altogether, 225 F_3 progenies were inoculated with this race and 26 were resistant, 86 segregating, and 113 susceptible. The results for both generations indicate a very different basis for the inheritance of smut resistance as compared with the F_2 and F_3 generations inoculated with Avenae-1, Levis-1, and Levis-7.

Results with Ustilago avenae, Race 10.—Both Navarro and Hull-less are resistant to the Red Rustproof race of loose smut, 125 plants of Navarro having been inoculated with various collections belonging to this race and none infected. In similar tests 53 plants of Hull-less have given negative results.

A very small number of F_2 plants was inoculated with one collection of the Red Rustproof race, none of them being infected. There were 25 F_3 progenies grown, inoculated with another collection of this same race of loose smut. Most of these progenies were resistant; three of them, however, contained one smutted plant, another progeny three smutted plants and, in another, slightly more than half of the plants were infected. It is evident that susceptible individuals may be obtained among third generation progenies, although both the original varieties are resistant.

HYBRID 91. NAVARRO \times BLACK MESDAG.—The second and third generations of this hybrid were inoculated with two races of covered smut and two of the loose.

Results with Ustilago levis, Race 7.—Black Mesdag is susceptible to this race of covered smut, 287 plants being inoculated, of which 193 (67.2 per cent) were infected. In two of the experiments rather low percentages of infection (40 and 43.7) were obtained; in the field in 1938 100 per cent of the inoculated plants were infected. In contrast to the results secured with Black Mesdag, Navarro proved resistant, 338 plants being inoculated and none infected. Altogether, 62 F_2 plants were inoculated and 3 (4.8 per cent) were infected. A total of 130 inoculated F_3 progenies was grown. The results indicate a much more complicated situation than a two- or even three-factor basis, and agree more closely with the assumption that at least five independent factors for resistance are involved. The correspondence between observed and expected results on this basis are as follows:

	Resistant	Segregating	Susceptible
Observed	97	32	1
Expected (781:242:1)	98	32	0

The occurrence of three infected F_2 plants in a population of 62 would not be expected, since only one smutted plant out of 1,023 should be found. A susceptible F_3 progeny in such a small population also would not be expected. The F_3 progeny classified as such, however, gave 83.3 per cent infection.

Results with Ustilago levis, Race 9.—Black Mesdag has proved to be susceptible to this particular race of covered smut. In the present experiments 81 plants were inoculated and 71 (87.6 per cent) were infected. Navarro, on the other hand, is resistant, 66 plants being inoculated and none infected. No F_2 plants were inoculated with this race. However, a total of 146 F_3 progenies was grown, and the data suggest a series of independent factors for resistance. Altogether, 130 progenies were resistant, 13 segregating, and 3 might be classified as susceptible. Ten of the F_3 progenies were retested, giving almost identical results as in the first experiment. The results do not fit very closely any particular formula, being nearest, perhaps, to an explanation on the basis of five factors.

Results with Ustilago avenae, Race 12.—Both the parental varieties are resistant to this race of loose smut and in these experiments 174 plants of Black Mesdag and 506 of Navarro were inoculated, no infected plants being observed in either variety.

There were 63 F_2 plants inoculated and 3 (4.7 per cent) were infected. A total of 130 F_3 progenies were grown, the results being as follows:

	Resistant	Segregating	Susceptible
Observed	81	46	3
Expected (37:26:1)	75.1	52.7	2

The F_2 data might be interpreted as either a two- or three-factor difference. On the other hand, the data for the F_3 progenies fit rather closely the assumption of three independent factors.

Results with Ustilago avenae, Race 10.—Both Black Mesdag and Navarro are resistant to the Red Rustproof race of loose smut, 37 plants of the former and 125 of the latter having been inoculated and none was infected. A series of 25 F_3 progenies of the hybrid was inoculated with a collection of this race. No infected plants were observed in any of the progenies.

HYBRID 92. NAVARRO \times GOTHLAND.—The second and third generations of this hybrid were inoculated with two races of loose smut.

Results with Ustilago avenae, Race 1.—In the course of the experiments 241 plants of Navarro were inoculated and none was infected, while 209 plants of Gothland were grown and 205 (98 per cent) were smutted.

There were 67 second generation plants inoculated with race 1 of the loose smut and of these 5 (7.4 per cent) were infected. These data suggest the presence of two factors for resistance since, on this assumption, the ratio between the normal and the

infected would be 15:1, or a total of 63 normal to 4 smutted plants. The data obtained for the third generation fit this interpretation, the results for 165 progenies grown being as follows:

	Resistant	Segregating	Susceptible
Observed	78	80	7
Expected (7:8:1)	72	83	10

Results with Ustilago avenae, Race 10.—Seventeen second generation plants were inoculated with Avenae 38, a collection which belongs to the Red Rustproof race. No infected plants were obtained. Along with these F_2 plants, 19 plants of Gothland and 17 of Navarro also gave negative results. Other collections of the Red Rustproof race have given similar results with these varieties.

In the same year 25 third-generation progenies, inoculated with another collection belonging to the Red Rustproof race of loose smut were grown. In one of the progenies a single infected plant out of a total of 23 was observed, and in another progeny 5 plants out of a total of 22. These results suggest that, although both parents are resistant, we may find, among a large number of F_2 plants, an occasional infected one and some F_3 progenies segregating or even susceptible to this particular race. Several independent factors would account for the resistance in the hybrid generations.

DISCUSSION.—The data for Hybrid 90 Navarro \times Hull-less, and Hybrid 92 Navarro \times Gothland, inoculated with race 1 of *Ustilago avenae*, fit quite well with the assumption of two independent factors for resistance. On this basis we would expect 6.25 per cent of the F_2 plants to be infected, and 56.25 per cent of the F_3 progenies would be classified as segregating and susceptible. In Hybrid 90, 7 F_2 plants out of 74 inoculated (9.4 per cent), and in Hybrid 92, 5 F_2 plants out of 67 (7.4 per cent) were infected. In the first hybrid 56.22 per cent of the F_3 progenies were classified as either segregating or susceptible; the progenies also separated into the two groups according to expectation. In Hybrid 92, 52.7 per cent of the F_3 progenies were included in the segregating and susceptible group, a close correspondence to the two-factor explanation.

The resistance of Hybrid 90 Navarro \times Hull-less to races 1 and 7 of *U. levis* appears to depend upon three independent factors; the data for the F_2 generation as well as for the F_3 closely fit this interpretation. In the F_2 generation we would expect 1.55 per cent of the plants to be infected. Actually, 5.7 per cent, or 4 F_2 plants out of 70 inoculated with race 1 were smutted and 3 per cent, or 4 F_2 plants out of 132 inoculated with race 7 were infected. In the third generation, 42.17 per cent of the progenies would be expected to be segregating or susceptible and, according to the data obtained, 44.1 per cent of the 265 F_3 progenies inoculated with race 1 and

45.1 per cent of the 226 F_3 progenies inoculated with race 7 belong to these two groups.

Resistance in Hybrid 91 Navarro \times Black Mesdag, inoculated with races 7 and 9 of the covered smut, doubtless rests on several factors, possibly as many as five. The data for the F_2 generation might suggest a three-factor difference, but the number of segregating and susceptible progenies in the F_3 generation is far too low for this explanation. The data for this hybrid, inoculated with A-12, indicate a three-factor situation.

The results with Hybrid 90 Navarro \times Hull-less, inoculated with race 12 of the loose smut, are very different from those just described. In the second generation, 121 plants were inoculated and 62 (51.2 per cent) were infected. The results indicate that susceptibility may be dominant over resistance; the percentage of infection, however, does not suggest any simple factor relation. Among the 225 F_3 progenies inoculated, only 26 were resistant, the remainder being classified as segregating or susceptible. Of these progenies, 86 were classified as segregating, giving less than 50 per cent infection, and 113 as susceptible, giving 50 to 100 per cent infection.

The results with this hybrid, inoculated with *Ustilago avenae*, race 12, are somewhat similar to data reported for other crosses (Reed, 1932). Gothland \times Hull-less gave a high percentage of infection of the F_2 plants inoculated with Levis 1. In the F_3 generation there was a very marked excess of segregating and susceptible progenies over the resistant. Similar results were obtained with Monarch \times Hull-less inoculated with Avenae 1. Schattenberg (1934) reports several cases where there was a very great shortage of resistant F_3 progenies and a corresponding large number of segregating and susceptible. Torrie (1939) obtained a similar result in the hybrid Iowa 444 \times Bond, securing 39 per cent infection of the F_2 plants and 24 resistant, 166 segregating, and 60 susceptible F_3 progenies out of a total of 250 grown.

No adequate explanation of these results has been given. Schattenberg (1934) assumes a single factor difference. Torrie (1939) suggests a 4:11:1 relation, including in the resistant group a large number of F_3 progenies which give low percentages of infection; he also assumes a factor for susceptibility as epistatic to a factor for resistance.

Marcy (1937) obtained somewhat similar results in sorghum hybrids between Feterita and other varieties susceptible to *Sphacelotheca sorghi* (Link) Clinton. She suggests the interaction of a factor for susceptibility (S) in the susceptible varieties, and a factor for resistance (B) brought in by Feterita. Under environal conditions highly favorable for infection, S has been demonstrated to be epistatic to B for segregation in the F_2 generation, giving approximately the ratio of 13 infected to 3 normal plants. Under conditions less favorable for infection, the F_2 ratios were nearly reversed, approaching 3 resistant to 1 susceptible. She concluded that hybrid plants

containing both the S and B factors were unstable in their infection reactions, and that the epistasis of S over B, or B over S, was determined by environal conditions during the germination period.

Many oat crosses have been reported in which the data for the F_2 and F_3 generations indicate a single factor for resistance. The data published for hybrids of Hull-less \times Black Mesdag, Silvermine \times Black Mesdag, and Early Champion \times Black Mesdag, inoculated with Avenae race 1 and Levis race 1, give results indicating a single factor for resistance (Reed, 1928, 1934). Similar results have been obtained for Fulghum \times Black Mesdag inoculated by Avenae race 12 (Reed, 1935), Gothland \times Black Mesdag, and Danish Island \times Black Mesdag inoculated with Avenae race 1, Green Mountain \times Monarch inoculated with Avenae race 1 and Levis race 3 (Reed, 1941). Von Rosenstiel (1929) records data for four hybrids in which the explanation is based on a single factor. Coffman *et al.* (1931) offer this explanation for hybrids of Markton \times Early Champion.

Two factors for resistance are assumed for other types of oat crosses. This is the explanation for the hybrid (Victory \times "Hybrid") inoculated with *U. avenae* and *U. levis* (Welsh, 1931). Hybrids of Markton \times Aurora, Ligowa, Scottish Chief, Swedish Select, and Victory were also explained on the two-factor basis (Coffman *et al.*, 1931).

Three factors are the probable explanation for other oat crosses. Iogren \times Markton and Silvermine \times Markton, as recorded by Coffman *et al.* (1931); Markton \times Colorado 37 (Austin and Robertson, 1936); Fulghum \times Black Mesdag (Barney, 1924); von Lochows Gelbhafer \times Red Rustproof (Nicolaisen, 1931). Schattenberg (1934) gives data on a hybrid in which a three-factor explanation seems adequate. Stanton, Reed, and Coffman (1934) reported on certain hybrids which might be explained on this same basis—Monarch Selection \times Black Mesdag inoculated with Levis race 1, and Richland \times Markton, Markton \times Iogold, and Cornellian \times Markton, inoculated with Avenae race 1.

Finally, there are several cases where four or more factors are necessary for a satisfactory explanation—Red Rustproof \times Abundance and Black Tartarian, inoculated with *U. levis* (Gaines, 1925); Richland \times Markton, Markton \times Iogold, and Cornellian \times Markton, inoculated with Levis race 1, and Markton \times Black Mesdag inoculated with Avenae race 1 and Levis race 1 (Stanton, Reed, and Coffman, 1934).

Third generation progenies of all three hybrids were inoculated with the Red Rustproof race, Avenae 10. No infected plants were observed in Hybrid 91. In Hybrids 90 and 92 an occasional progeny contained 1 to 13 infected plants.

SUMMARY

The Navarro oat variety is resistant to all the known races of *Ustilago avenae* and *U. levis* with

which tests have been made. Its marked resistance has been utilized in oat-breeding investigations, and the variety is interesting for the analysis of the inheritance of resistance to smut.

Hybrids of Navarro and Hull-less inoculated with *U. avenae* race 1, based on F_2 and F_3 data, indicate a two-factor relation for inheritance of resistance. A three-factor difference is indicated for these hybrids when inoculated with *U. levis* race 1 and race 7.

The hybrids of Navarro and Hull-less, inoculated with *U. avenae* race 12 differ markedly from the results just mentioned. There is a high percentage of inoculated F_2 plants infected; in the F_3 generation there is a very small number of resistant progenies and a great excess of segregating and susceptible.

In hybrids of Navarro and Black Mesdag, five factors for the inheritance of resistance to *U. levis* races 7 and 9, and three factors for *U. avenae* race 12 are indicated.

In the hybrid of Navarro and Gothland, inoculated with *U. avenae* race 1, two factors are indicated.

All of the parental varieties, Navarro, Hull-less, Black Mesdag, and Gothland, are resistant to the Red Rustproof race of loose smut, Avenae 10. An occasional F_3 progeny of Navarro \times Hull-less and Navarro \times Gothland contains infected plants. No smutted plants were found in the F_3 progenies of Navarro \times Black Mesdag.

CARBON DIOXIDE EVOLUTION DURING THE INDUCTION PERIOD OF PHOTOSYNTHESIS¹

James Franck

IN THEIR report of experiments on the quantum efficiency of photosynthesis, Emerson (1939) and Emerson and Lewis (1941) have described some transients in the exchange of CO₂ which occur at the beginning and end of an illumination period. These transients bear some resemblances to the previously known induction period for photosynthesis and to the pickup phenomenon discovered by McAlister (1937). The induction and pickup phenomena are relatively small effects and have generally been interpreted as perturbations in the photosynthetic process and have accordingly been incorporated in theories of the kinetics of photosynthesis. The transients observed by Emerson and Lewis are under proper circumstances large effects: they report that at the beginning of illumination an "outburst" of CO₂ occurs, and that for a few minutes the rate of CO₂ evolution may be ten times the rate of photosynthesis. These phenomena, they believe, suggest that the plant contains a "reservoir" for CO₂ which is emptied rapidly by a photochemical reaction and is slowly refilled during a dark period.

Emerson and Lewis doubt that there is sufficient evidence for believing that the CO₂ reservoir has any direct connection with the photosynthetic machinery of the plant. They also suggest that the induction and pickup phenomena of carbon dioxide may be simply somewhat subdued manifestations of the reservoir. Consequently, they are led to question their significance for the photosynthetic theory. These criticisms are directed particularly at the induction and pickup as observed by McAlister (1937), by Aufdemgarte (1939), and by McAlister and Myers (1940), since their measurements are confined to the exchange of CO₂, but, if justified, would also invalidate the theory of the induction period developed by Franck, French, and Puck (1941) which is based on the same and similar measurements and on correlated anomalies of the chlorophyll fluorescence.

I feel unable to concur in this scepticism regarding the value of these studies of induction phenomena in

photosynthesis. It seems to me rather that one may regard Emerson and Lewis' observations as contributing further evidence in support of our interpretation of the induction period.

First, we shall give our objections to the explanation which Emerson and Lewis propose for the outburst. The facts observed by these authors and which have to be explained are the following: at all intensities the CO₂ outburst² occurs during the first two minutes of irradiation. In the region of small light intensities its rate is proportional to the light energy absorbed and its quantum yield is about one. A transition from lower to higher intensities produces a new outburst even after a long irradiation at the lower intensity. The rate of O₂ production (according to the curves published) is negligible during the CO₂ outburst but rises rapidly to its final value as the rate of the outburst declines.³ The final rate is proportional to the light intensity (as long as the latter is small compared with saturation intensities) and does not show the same dependence on the previous treatment of the algae as does the CO₂ outburst. Finally with continued irradiation, at all light intensities, the photosynthetic quotient approaches the value one.

If, as Emerson and Lewis assume, an unidentified substance X, which has no direct relation to photosynthesis, is the source of the CO₂ evolved, its concentration at the beginning of the irradiation period must be so great that it almost completely displaces from the chlorophyll those substances normally photosynthesized, for otherwise the quantum yield for the splitting off of CO₂ could not approach unity. On the other hand, it is evident that after an irradiation of two minutes X no longer competes with the substrate of photosynthesis, for then the rate of oxygen

² The term CO₂ outburst refers only to the strong main anomaly in the rate curve of the CO₂ exchange. A discussion of the small irregularities which follow the main maximum will be found further in the discussion.

³ One has to bear in mind, though, that according to Emerson and Lewis not too much importance should be attached to the precise shape of the rate curves of the O₂ production.

¹ Received for publication December 24, 1941.

Supported by the Fels Foundation.

production is normal at all light intensities. Consequently, we should conclude that after two minutes of irradiation, regardless of the intensity, the concentration of X is much smaller than that of the substrate of photosynthesis. But this conclusion is contradicted by the fact that a transition to a higher intensity produces a new outburst, which could occur only if X were still present.

One might attempt to avoid this contradiction by assuming that a small part of the chlorophyll is separated from the remainder and that the bulk of the chlorophyll is responsible only for photosynthesis while the smaller portion sensitizes the splitting of CO_2 from X. The quantum yield of about one must then be explained by a chain reaction. But a chain is very implausible for this type of reaction. Photooxidation chains are excluded, since the corresponding oxygen uptake is not observed, and other chains involving radicals as chain carriers and delivering CO_2 as the end product are difficult to imagine. The other type of chain, in which the energy liberated in one link of the chain activates the next one until the proper length is reached, seems to be excluded since such chains do not occur in a condensed system in which the energy is dissipated very quickly. In addition this hypothesis fails to explain the lack of oxygen production during the outburst, and requires additional assumptions to explain why the reservoir partially drained by a weak illumination is not filled up again in the dark in about the same time needed by the outburst to drain it.

Hence, we discard the hypothesis that the substance X, from which CO_2 is produced during the outburst, is one which is not intimately connected with the photosynthetic apparatus.

We now present the evidence for regarding the CO_2 outburst as a special form of the short induction period which differs from the normal cases only because of the peculiar conditions resulting from the special treatment of the algae which make the outburst prominent. If we accept this point of view it becomes self-evident that the short induction period and the outburst show the same general behavior. The duration of the outburst is the same as that of the normal induction period; the time course of both phenomena is independent of light energy, and they both show the very specific quality of being excited stepwise if the light intensity is increased stepwise. Furthermore, from our theory of the induction period we can obtain a detailed understanding of the outburst. We shall not repeat here the whole theory of the induction period⁴ and its experimental basis, but merely recapitulate its main features and then apply them to the present problem.

⁴ The theory of the short induction period is presented in a paper of J. Franck, J. French and F. Puck, *Journal of Physical Chemistry*, 1941. The idea that the induction phenomena are caused by a temporary deficiency of the oxygen splitting catalyst on which the theory is based is taken from a paper of H. Gaffron, *Naturwissenschaften*, 1937. The theory of the general kinetics of photosynthesis is presented in a paper of J. Franck and K. F. Herzfeld, *Jour. of Phys. Chem.*, 1941.

According to the theory, all the anomalies of the photosynthetic gas exchange and of the chlorophyll fluorescence during the short induction period are caused by a temporary deficiency of the oxygen splitting catalyst (called catalyst C in our treatment of the kinetics of photosynthesis). Catalyst C is deactivated in the dark and becomes reactivated during the beginning of an illumination period by a reaction with the reduced photosynthetic product. The duration of the readjustment is independent of the light intensity because, to prevent a limitation at small light intensities, only a small proportion of catalyst C need be active, while at higher intensities a correspondingly higher proportion is required. The limited efficiency of catalyst C during the induction period causes an accumulation of the photoperoxides. The accumulated peroxides react, under the conditions prevailing in most of the cases, with a metabolic product and transform it to a partially oxidized product, which in its turn acts as a poison for other catalysts involved in photosynthesis. In this way, the total photosynthetic yield is quickly reduced to a very low value. The recovery of photosynthesis occurs on the reactivation of catalyst C and an oxidative removal of the poison; the time required for this is about two minutes. That the photosynthetic yield is abnormally low during the induction period does not mean, however, that the number of photochemical reactions is small. We suppose, on the basis of quite independent evidence (Franck and Herzfeld, 1941), that the freshly formed photoproducts are chemically unstable and fall back to their original state if they are not stabilized quickly by a chemical reaction in which a catalyst "B" is involved. Since catalyst B is especially susceptible to that poison produced during the induction period, most of the freshly formed photochemical products undergo back reactions during the induction period and dissipate as heat the energy obtained photochemically.

The energy liberated by each back reaction is considerable; back reactions to the state of a loosely bound compound are, therefore, likely to break up such products. This is the case with the lowest intermediate of photosynthesis, which is an organic molecule loosely connected with a CO_2 molecule. According to Kamen, Ruben and co-workers (1939 and 1940), it is a reversibly carboxylated product written conventionally as RCOOH . As the result of a back reaction, it dissociates into RH and CO_2 . Several quite different sets of observations can be explained by means of this CO_2 splitting process. Since the rate of back reactions is great during the induction period, the possibility of a CO_2 evolution during that period is an important point. It is questionable whether under normal conditions a CO_2 evolution actually occurs during the induction period. Since apparently the rate of O_2 production (Blinks and Skow, 1938) runs parallel to the rate of CO_2 uptake (McAllister, 1937; McAllister and Myers, 1940; Aufdemgarten, 1939), we concluded that the splitting off of CO_2 is normally compensated by the carboxylation reaction which takes place with the

help of a catalyst A which is present in abundance so that no outburst of CO_2 occurs. In other words the experiments carried so far seem to indicate that the oxidized metabolite does not act as a strong poison for catalyst A involved in the carboxylation reaction. According to our point of view, the experiments of Emerson and Lewis are simply observations of induction periods carried out under conditions such that the carboxylation reaction is temporarily unable to compensate the photochemical decarboxylation of RCOOH . The condition necessary is the presence of an unusually great amount of RCOOH . Its concentration must be great compared with that of the other intermediates of photosynthesis, otherwise the quantum yield for CO_2 liberation could not be about unity. All the light absorbed is diverted to RCOOH ; the other intermediates are crowded away from the chlorophyll. That favors, of course, the evolution of carbon dioxide, because now all back reactions occurring during the induction period will result in splitting off CO_2 , causing a yield about ten times greater than normal.

If this be true, we should expect a strong recarboxylation, that is, a strong carbon dioxide absorption immediately upon the end of the induction period. Catalyst A is certainly able at this moment to handle an amount of RH equal to the amount of RH liberated during the outburst in about one minute. (Its efficiency is known experimentally from the fact that it still is not limiting at the high rate of photosynthesis prevailing at light saturation.) Since such a period of an abnormally strong uptake of CO_2 does not appear in Emerson and Lewis' curves, we are forced to assume that not only RCOOH dissociates under the conditions prevailing during the outburst, but that the resulting RH is excluded from further participation in the carboxylation reaction. We believe that this elimination is caused by the unusually great momentary concentration of RH which is the result of the high rate of its liberation during the outburst. If RH is indeed a carbohydrate molecule, its excess might be removed by a polymerization reaction.

The time course of the CO_2 exchange during the illumination period after the expiration of the outburst is normal if one takes into account that, even after the outburst, some surplus of the concentration of RCOOH over that of the higher intermediates is still present.⁵

A few words may be added to explain the time

⁵ During the steady state of photosynthesis the concentration of RCOOH is just equal to that of the other intermediates, and this even distribution remains normally unaltered after dark pauses of about one-half hour. (This latter condition is not fulfilled under the special conditions prevailing in Emerson and Lewis' experiments as will be discussed below). Therefore, if photosynthesis is resumed, no irregularities in the rate curves are observed, which may be attributed to a redistribution of the concentrations of intermediates. If on the other hand, conditions are chosen such that an uneven distribution is produced, the expected irregularities (called long induction periods) occur in the rate curves and have a duration which is inversely proportional to the final rate of photosynthesis. The latter part of

course of the CO_2 exchange in the dark period following an exposure to light for about one-half hour. Emerson and Lewis observed that a slow uptake of carbon dioxide occurs, which is superimposed on the normal carbon dioxide production by respiration for about forty minutes. This uptake of CO_2 is only observable if enough oxygen is present to allow an undisturbed respiration of the algae. The CO_2 accumulated in that way is available for a new outburst if irradiation is resumed. This carbon dioxide uptake in the dark is an entirely separate phenomenon from the pickup of CO_2 as observed by McAllister and Myers (1940) and Aufdemgarten (1939). The normal pickup is a process in which RH, liberated by photosynthesis or by back reactions during the illumination period, combines with CO_2 in the dark directly after the light is turned off. Free RH is only available at that time if catalyst A was limiting during the irradiation period. In the present case catalyst A was not limiting in the last twenty-five minutes of the prolonged irradiation with weak light and, consequently, free RH should not be present at all. One has, therefore, to find another explanation for the slow uptake of CO_2 in the dark. It is very probably caused by a slow new formation of RH. The concentration of RH present at each moment is so small that only the carboxylation reaction which employs catalyst A is effective in removing RH. The side reaction mentioned above, wherein RH is eliminated if present in high concentrations, can be neglected. While it would be premature to speculate at this time about the nature of the process of the formation of RH, it seems significant that it is connected with the respiration process. The formation of RH by metabolic processes and also its consumption by the side reaction thus indicated by the observation of Emerson and Lewis will certainly become of importance in further studies of the carboxylation process which precedes photosynthesis.

SUMMARY

Emerson and Lewis observed that with algae under special conditions a carbon dioxide evolution occurs at the beginning of an illumination period. They are inclined to suppose that this process has no direct connection with photosynthesis. The present paper is intended to show that what Emerson and Lewis (1941) observed is a special case of the normal induction period, and its interpretation is closely related to that given by Franck, French, and Puck (1941) for other induction phenomena. From this the time course of the CO_2 exchange as observed by Emerson and Lewis (the second weak maximum of the curve followed by the slow transition to the steady state of CO_2 uptake) shows these typical anomalies. It is in accordance with expectation that such anomalies are absent in the rate curves for the O_2 production. The rate of O_2 evolution depends on the distribution of the concentrations of the hydrogenated and dehydrogenated hydrogen donors and not on the relative concentrations of the hydrogen acceptors (RCOOH and its partially reduced derivatives). Only great anomalies in the absolute concentration of the latter will influence the rate of the oxygen production in an indirect way.

point of view the carbon dioxide evolution is explained by back reactions and thus lends support to the principle advanced by Franck and Herzfeld (1941) that back reactions influence kinetics of

photosynthesis whenever catalytic limitations occur.

AN ANALYSIS OF THE COMPARATIVE RATES OF CELL DIVISION IN VARIOUS PARTS OF THE DEVELOPING CUCURBIT OVARY¹

Edmund W. Sinnott

THE DETERMINATION of comparative rates of cell division in different tissues or regions is an important problem in plant development but is difficult to accomplish by direct mitotic counts. Another method of attacking it is to determine the increase in cell number for given tissues over a given period. The young cucurbit ovary is particularly good material for such a study. Its various regions are sharply delimited, and their volumes can be measured with fair accuracy. Average cell volume can also be measured for each, and if region volume is divided by cell volume, the approximate number of constituent cells at any stage may be calculated. In a previous paper (1939) the author has made an analysis of cell size in various regions of the cucurbit ovary—epidermis, outer wall, inner wall and placental region—during its development from early primordium to maturity, in twelve lines belonging to four genera. The purpose of the present study was to measure the volumes of these regions during early development and to determine the increase in cell number, and thus the comparative rate of cell division, for each.

In the earlier paper it was shown that the size of the epidermal cells remains relatively constant

throughout most of the growth period, but that in the other tissues cell size increases during development, and more in the inner regions of the ovary than in the outer ones. In early growth cell size increases much less rapidly than organ size, so that most of the ovary growth must be by cell multiplication. At a given point, characteristic for each region and race, division ceases and much more rapid cell enlargement begins, the size of cell and organ thereafter increasing equally. In all races but one (*Cucumis Anguria*) cell division persists in all regions until the ovary diameter reaches at least 10 mm. Accurate measurements can be made on ovaries as small as 2 mm. in diameter. The developmental period of this organ from 2 mm. to 10 mm., therefore, serves as a convenient one for a comparative study of increase in cell number. In the paper already cited (1939, table 1), cell diameters for each region in all twelve races are given for ovary diameters of 2 mm. and of 10 mm., and these figures have been used in the present study. It should be remembered that cells of only the ground parenchyma and epidermis are considered, but that these constitute the bulk of the young ovary.

METHODS.—Volumes of regions were calculated from diameter measurements of equatorial cross sec-

¹ Received for publication December 31, 1941.

tions (fig. 1). At the two ovary sizes, the average diameter was determined for the placental region and for the circle of vascular bundles in the wall. The region between placenta and bundles, designated as "inner wall" and "middle wall" in the previous paper, is here treated as one layer, since the limit between the two tissues is not sharp enough for accurate measurement. This region in the present paper

Fig. 1. Diagram of cross section of cucurbit ovary, showing the three inner regions measured. A, outer wall, between ring of large bundles and epidermis; B, inner wall, between placenta and bundle ring; C, placental region.

is distinguished as the "inner wall." The region between the vascular bundles and epidermis, as before, is termed the "outer wall." The average of the diameters for cells of the inner and middle wall in the previous paper was used as the cell diameter for the inner wall.

The absolute volume of the ovary and its various regions was impossible to determine from the data, but the cross sectional area of each at the equator could be measured with accuracy from these diameters. For purposes of comparison, cell number for each region at the two ovary diameters could be calculated from an equatorial slice, in thickness proportional to its diameter. The same regional volume relationships obtain, however, if the ovary and its regions are treated as concentric spheres; and since in all lines but one the ovary is approximately spherical, regional volumes and cell numbers have been calculated on this basis and thus approximate the actual values. The present study is concerned with comparative, rather than absolute, increases in cell number.

The volume of the placental region was determined directly from its diameter by the formula for spherical volume, $\frac{4}{3} \pi r^3$. Inner wall volume was found by subtracting this placental volume from the volume of a sphere the diameter of which was that of the bundle ring. This latter volume, in turn, was subtracted from the total ovary volume to obtain the

volume of the outer wall. Ovary surface was determined from its diameter, as $4 \pi r^2$.

Cell diameters were cubed to give approximate volume. Cell number for each region except the epidermis was determined by dividing this cell volume into the region volume. For the epidermis, cell number was found by dividing the surface area of the ovary by the surface area of the epidermal cells, found by squaring their diameters.

For comparative purposes the values reached by the methods here described are reasonably satisfactory, and the consistent relationships which they show give confidence in their essential accuracy.

From the ratio of cell number at 10 mm. to cell number at 2 mm., for each region, the number of cell generations can be computed by finding what power of 2 this quantity is. Thus if cell number at 10 mm. is 30 times that at 2 mm., there have been approximately 4.9 cell generations, since $30 = 2^{4.9}$. This value can readily be determined by dividing the logarithm of 30 (1.4771) by the logarithm of 2 (.301). That such a figure can be used as a measure of the number of cell generations depends on the assumption that every cell lineage is dividing at approximately the same rate. This seems probable, since the cells in a given region are similar in character and show only a limited range in size. It is not necessary to assume that division is rhythmic or simultaneous and there is no evidence that such is the case.

In Line G (*Cucumis Anguria*) where, for all regions except the epidermis, cell division ceases and vacuolation begins before the ovary reaches a diameter of 10 mm., the cell diameters at this ovary size obviously could not be used, and this line was omitted from the present study.

TABLE 1. Diameters in millimeters of placenta and vascular ring at the two ovary diameters and in the eleven lines.

RESULTS.—In table 1 are given for the eleven lines the diameters of placenta and vascular ring at ovary diameters of 2 mm. and 10 mm. The first seven lines are of *Cucurbita Pepo*. Of these, TA, SP, and SRC are small fruited; CF, M35 and MT are large fruited, and 103 is intermediate. Lines CN, CL and GB are of *Lagenaria vulgaris*. CL is the "Hercules Club," much longer than wide, and GB is one of the

constricted "bottle" races. *WM* is a watermelon (*Citrullus vulgaris*).

Table 2 presents the basic data of the paper. For each of the eleven races, and the two ovary diameters, there have been calculated the volumes in cubic millimeters of placental region, inner wall and outer wall; the average volume in cubic micra of the cells of each; the surface area of the epidermal cells in square micra; the cell number in each region; the ratio of the values for the larger ovary to those for the smaller; and the number of cell generations which would produce the increase in cell number.

Discussion.—A number of facts as to cell multiplication emerge from these data, notably that cell number increases at essentially the same rate in all regions, regardless of cell size; and that cell number and ovary surface tend to increase at the same rate. These facts have certain implications.

Cell size and division rate.—Even in the 2-mm. ovaries the cells of the inner regions are considerably larger than those of the outer ones, and these differences are accentuated during development by the more rapid increase in size of these inner cells. In such tissues each pair of daughter cells, before they divide again, evidently grow to a greater size than was reached by their mother cell. In the 10-mm. ovary as compared with the 2-mm. one, the cells of the outer wall are, on the average for eleven lines, about three times as large, those of the inner wall about five times as large, and those of the placental region between eight and nine times as large. Epidermal cell size shows little or no increase, or may even decrease slightly.

The ratio of increase in size of the various regions closely parallels that of their cells. These ratios differ markedly between regions and among the various lines, but the remarkable fact is that the relation of increase in regional volume to increase in cell volume (which evidently is the same as the ratio of increase in cell number, given in the table) tends to

be constant. Thus in Line *TA* ovary surface increases 25 times and epidermal cell area 1.08 times; outer wall volume 80.2 times and cell volume 3.17 times; inner wall volume 149 times and cell volume 6.82 times; and placental volume 177 times and cell volume 8 times. Despite these differences the ratio of region increase to cell increase is relatively uniform, being 23.23, 25.33, 21.82 and 22.13. The correlation between cell volume and region volume is close throughout. This must mean that increase in cell number, and thus rate of cell division, is much the same in the four regions studied. In the epidermis, cell number in the large ovary is, on the average for the eleven lines, 24.39 ± 1.57 times as great as in the small; in the outer wall, 26.52 ± 2.29 times as great; in the inner wall, 26.37 ± 1.94 times as great; and in the placental region, 25.18 ± 2.18 times as great. The average number of cell generations for these four regions is, therefore, $4.58 \pm .09$, $4.68 \pm .12$, $4.66 \pm .12$, and $4.60 \pm .12$. This close similarity in rate of cell division between big-celled regions and small-celled ones makes it clear that in this material, at least, increased cell size does not result in reduced division rate. In large cells the amount and rate of growth in each cell generation is evidently greater than in small cells, but whether this is in protoplasm or only in the vacuole is not known. Rate of cell division seems to be determined by some factor independent of cell size and operative throughout the entire organ.

It should be remembered that these figures are concerned entirely with the *comparative* rates of division and not with absolute rates. The four regions in a given ovary have obviously been growing for the same length of time, and increase in cell number in each can therefore be used as a fair measure of comparative division rate between regions. It cannot be used to compare absolute rates either as between regions or lines, since the length of the growth period between diameters of 2 mm. and 10 mm. is not given. As a matter of fact this is much the same in all lines.

That the relatively large and vacuolate cells of the innermost regions are still dividing is indicated by the fact that newly formed division walls can easily be recognized among them. In well-fixed material, mitotic figures are also evident. The author (and Bloch, 1941) has recently called attention to the frequent occurrence of divisions in comparatively large, vacuolate cells, and the tissues here considered are certainly not exceptional.

Cell number and ovary surface.—Not only is the rate of increase in cell number much the same between the various regions in a given line but it is very similar in the various lines. The average of all the ratios of increase is close to 25 times. This figure is also the ratio of increase of ovary surface, for as the diameter increases five times (from 2 to 10 mm.) the surface area of the ovary increases as the square of five. In other words, cell number throughout the ovary increases at approximately the same rate as does ovary surface.

Since increased surface makes possible increased gas exchange between ovary and atmosphere, there may be a physiological basis for this close relation between surface area and cell division. Not enough is yet known as to the relation between rate of respiration and the surface and volume of the fruit to make possible any definite conclusions in this regard.

This relation between cell number and ovary surface may have its origin in the unique behavior of the epidermis. All divisions in this tissue are anticlinal (perpendicular to the surface), and since cell size remains essentially constant here, division must be proceeding at just the rate which will maintain this cell size. As soon as two daughter cells reach this size they again divide, and epidermal cell number thus keeps direct pace with ovary surface. It may be that the constant cell size in the epidermis is a physiologically optimum one and that the rate of division necessary to maintain it acts as "pacemaker" for divisions in the inner and less closely regulated tissues.

The gradient in cell size.—These internal regions, which constitute the bulk of the ovary volume, must increase as the cube of the diameter, while the surface increases only as its square. Thus the volume of the 10-mm. ovary is 125 times as large as that of the 2-mm. one, while its surface is only 25 times as large. Since the cells of the inner tissues are increasing in *number* no faster than those of the epidermis (which keep pace with the surface and maintain a constant size), it is evident that their volume must be five times as great. This is true, in the aggregate, but the size increase is not distributed evenly, being considerably below five times in the outer wall and considerably above this in the placenta. This gradient may perhaps be related to the increased concentration of growth substance in the interior of the ovary which has been reported by Gustafson (1939), or to gradients in vitamin concentration, respiratory rate, pH, osmotic concentration, or other variables.

The similar gradient in cell size commonly observable in the primary parenchyma of stems and other massive organs may be due to the same causes—uniform rate of cell division throughout, constant epidermal cell size, and necessary increase in size of interior cells. How the variables of organ surface, cell division and cell enlargement are related is not clear, and is evidently an important problem in developmental physiology.

Progressive increase of cell size toward the center of the ovary and constant division rate result, as has been shown above, in a relatively greater increase in volume of the innermost regions and a relatively lesser increase of the outer ones. This also seems to occur commonly in massive parenchymatous organs. The writer has shown (1936) that in several stems, both of ferns and of higher plants, the pith is relatively larger and the cortex relatively smaller in later developmental stages than in earlier ones and in large stems than in small. Such differential growth between regions must evidently involve a regulation of plane of division in the more slowly growing regions. Since the placental region grows faster than

the inner wall, for example, the cells of the latter would be compressed were it not for the fact that there is among them an excess of radial divisions which increases the circumference of the tissue relative to its radius. The factor involved may be simply mechanical pressure, since it is well known that a cell tends to divide parallel to the direction of compression.

These changes in proportion with increasing size, in primary tissues, call to mind the suggestion of Bower (1930) that the changed surface-volume relationship in organs of different size are important factors in producing increased structural complexity. If, for example, constant cell size (as of tracheids or sieve tubes) is physiologically important in the interior of an organ which is enlarging, either in development or evolution, a greater frequency of cell division must take place within it than would normally occur; and if rate of division is proportional to surface, as the present study suggests, this increased division might be related to the increases in tissue surface, and to the resulting convolutions described by Bower in many enlarging structures.

Exceptional cases.—In a number of lines there are exceptions to the two general rules that in all regions cell multiplication occurs at the same rate and that increase in cell number is proportional to organ surface.

Conspicuous is the case of line *CL*, a race of "Hercules Club," narrowly cylindrical in shape. Its cell volumes at an ovary diameter of 10 mm. are considerably too large as compared with one of 2 mm., increasing (on the average of all regions except the epidermis) about 8.8 times as compared to the expected 5 times. The average increase in cell number is, therefore, only about 15 times instead of the usual 25 times. In this race, however (unlike the others studied), length grows considerably faster than width, so that at a diameter of 10 mm. the length of the ovary, and thus its actual volume, is about 5 times as great as it would be if all dimensions were growing at the same rate. At a diameter of 2 mm. ovary length is 10 mm., but at a diameter of 10 mm. its length is 250 mm. The volume of ovaries at these diameters is obviously much greater than spherical ones of the same diameter would be. Absolute volumes of the ovary and its three inner regions were determined, assuming them to be cylinders; and from these values, the volumes of regions and cells were determined, by extrapolation, for ovary volumes equivalent to those of spheres 2 mm. and 10 mm. in diameter. Volume relations are thus comparable with the other lines. Actual surface area, corrected for shape, and epidermal cell area, were similarly determined. This method assumes that rate of increase in cell and region is constant from small ovary sizes to the larger one here involved, and all facts indicate that this assumption is sound. After the corrections thus made for line *CL*, it was found that the increase in cell number in the placental region was 19.1 times, in the inner wall 20.7 times, in the outer wall 20.5

times, and in the epidermis 26.1 times, with generation numbers of 4.25, 4.37, 4.36, and 4.70, results agreeing much more closely with those in the other lines. Even with this correction, cell number increases somewhat less than expectation and cell size somewhat more. Evidently the radically changed form of the ovary has modified the usual developmental schedule.

Line *GB* has relatively more cell multiplication than the average, the increase in cell number being over 31 times. Ovary surface, because of the progressive constriction in ovary shape, increases more than would that of a sphere, and increased cell division is perhaps a result of this.

In line 103 the increase in cell number between the two ovary sizes in all regions is consistently high (averaging 40.6 times) and cell size is correspondingly low. This line is distinguished from the rest by being the only one with a "bush" instead of a "running" type of vine, in having been inbred much longer, and in possessing a very warty surface. The latter trait, which very considerably increases the surface of the ovary and fruit, may perhaps be related to the marked increase observed in cell number.

There are several specific differences between lines, however, which do not affect the amount of cell increase. Thus line *CF* has only about half as many cells at comparable stages as does line *M35* and they are much larger, but the ratio of increase in cell number is essentially the same in both. Lines *TA* and *MT* differ greatly in final size and in the relative proportions of their tissues, but this does not affect the amount of cell multiplication in each.

Ovary pattern and fruit size.—The gradient in cell size and thus the relative sizes of the three internal regions, are markedly different in ovaries which are to develop into small fruits and in those which will make large fruits. The former have a much smaller placental region and a much thicker outer wall than the latter. Thus in the three small-fruited lines *TA*, *SRC*, and *SP* the average radius of the placental region in the 2 mm. ovary, is .527 mm. and of the outer wall .125 mm., but in the three large fruited lines *CF*, *M35* and *MT* these values are .587 mm. and .092 mm. The vascular ring and the regions in which division persists longest (the walls) thus have their cells considerably nearer the surface in the ovaries which are to grow to greatest size. There may be some connection between these facts.

SUMMARY

In eleven lines of cucurbits, belonging to three genera, the increase in cell number between an ovary diameter of 2 mm. and one of 10 mm. was determined for placental region, inner wall and outer wall by measuring the volumes of these regions and dividing each by its average cell volume; and for the epidermis by dividing ovary surface by average epidermal cell area. Cell division was still taking place in all these regions.

Between these two ovary sizes, epidermal cell volume remains essentially constant but in the other regions cell volume increases, and at a higher rate in the inner than in the outer ones.

Regional volume also increases faster in the inner than in the outer portion of the ovary, and there is a close correlation between rate of increase in cell volume and in regional volume.

Cell number thus increases at essentially the same rate in all four regions, so that rate of cell division is independent of cell size or position.

The increase in cell number in all regions tends to be the same as the increase in ovary surface. Physiological implications of this fact are discussed.

The greater increase in volume of inner cells as compared to epidermis is a necessary result of the fact that the ovary volume increases faster than its surface but that rate of cell division is constant. Possible reasons for the gradient in cell size from surface to center are suggested.

The relation of the results of this study to various problems of growth and differentiation are discussed.

DEVELOPMENT AND RELATIVE GROWTH IN OVARIES OF IRIS FULVA AND I. HEXAGONA VAR. GIGANTICAERULEA¹

Herbert Parkes Riley

STUDIES OF the morphological characters, geographical distribution and pollen fertility of a number of types of *Iris* in southeastern Louisiana (Viosca, 1935; Foster, 1937; Riley, 1938, 1939) have shown that *Iris fulva* Ker-Gawler, *I. hexagona* var. *giganticaerulea* (Small) R. C. Foster, *I. virginica* L. and *I. brevicaulis* Raf. are valid species, while *I. vinicolor* Small, *I. Thomasii* Small, *I. chrysophoenicia* Small and other species and varieties from that locality probably had a hybrid origin.² In studying these forms morphologically it was noticed that in *I. fulva* the ovaries and young capsules have six deep, wide grooves and six prominent, rather narrow ridges extending lengthwise, while in var. *giganticaerulea* the grooves are less deep and the ridges are wider and much less marked. In *fulva*, a cross section reveals a deeply indented outline while in *giganticaerulea* the indentations are much shallower and the outline appears scalloped. This difference is so marked that ovaries and young capsules of the two species can easily be distinguished. In spite of this noticeable difference during younger stages of development, the mature, fully grown capsules of both species are very nearly alike. The purpose of this in-

vestigation was to study how the fruit develops in both species and, by comparison, to determine, if possible, how inherent genetic differences may influence the pattern of development. The method of attack was to observe the shape of the ovary at the time it is first formed, to study the relative growth of the most important radii of the ovary throughout development and to determine what biological events are occurring during various stages of relative growth. The method of studying relative growth was suggested by Huxley (1932), who used it to compare the relative growth of an organ with that of the entire organism. Sinnott (1936) showed that this method is also applicable to dimensional relationships and not necessarily to a comparison of part with the whole. He pointed out that differences in shape of fruits of different species of gourd may be due to: (1) differences in shape which are visible as soon as the primordium of the ovary is formed; (2) constant differences in growth rate between length and width during development, even if the original sizes and shapes of the primordia are the same; and (3) differences in the final size of the fruit even though the original shapes and subsequent relative growth rates are the same in all species, provided that the value of *k* in Huxley's formula in the species studied is not 1.

MATERIALS AND METHODS.—The plants used for this investigation were wild plants growing in their native habitats in southeastern Louisiana. The study upon *I. fulva* is based upon a group of clones located about five miles north of Thibodaux and growing on the farthest slope of an alluvial ridge bordering a former deltaic stream. Collections were made at intervals of a week to ten days from early February until about the middle of August, 1938. The plants of

¹ Received for publication July 12, 1941.

This paper represents a joint contribution from the Departments of Botany of Tulane University, New Orleans, Louisiana, and the University of Washington, Seattle, Washington; it was aided in part by a grant from the New Orleans Academy of Science.

² In one paper by the author (Riley, 1939) it was stated that Ponchatoula Blue was considered a hybrid between *giganticaerulea* and *virginica*; this statement was due to an error in transcription, since Ponchatoula Blue is probably a hybrid between *giganticaerulea* and *brevicaulis* or the result of a backcross of such a hybrid to *giganticaerulea*.

I. hexagona var. *giganticaerulea* were growing in a fresh water marsh on the eastern side of Bayou Barataria near its intersection with Bayou Villars. Dates of collection were approximately the same as those for *I. fulva*, since it was the author's usual practice to visit Bayou Barataria on Thursday of each week and follow each collection there with a trip to Thibodaux the following Saturday; during July and August, when the capsules had matured, collections were less frequent.

To determine the measurements of the radii, fresh ovaries and capsules were cut into several pieces, fixed in FAA or Craf, sectioned, and stained; the measurements were obtained from camera lucida drawings of the cross sections.

To study the relative growth of two radii, their measurements were plotted on logarithmic paper after which the points were inspected for the purpose of fitting the most accurate curve. In most cases the curve appeared to consist of two or more straight

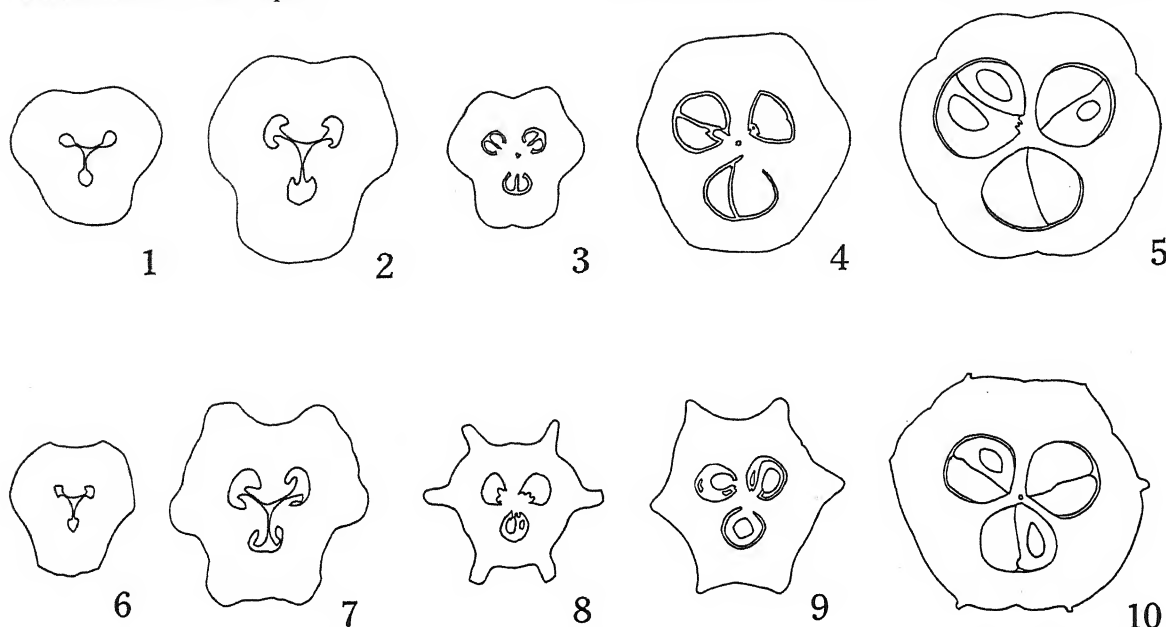

Fig. 1-10. Cross sections of *Iris* ovaries.—Fig. 1-5 are of *giganticaerulea* and figures 6-10 are of *fulva*.—Fig. 1 and 6. Cross sections of ovaries of young buds shortly after the organization of the ovary.—Fig. 2 and 7. Somewhat older buds showing the megasporangia growing into the locules.—Fig. 3 and 8. To obtain a picture of the changes in development which determine the shapes of the ovaries of the two species, 145 ovaries and capsules of *fulva* of various sizes from less than 1 mm. to 40 mm. wide, and 114 ovaries and capsules of *giganticaerulea* between 1.2 and 40 mm. were studied. Cross sections at the widest part were used and measurements were recorded of the following radii for each ovary and capsule: (a) the midrib of the carpel, used herein as the radius of reference in studying relative growth, (b) the septum between two carpels, one of which included the measured midrib, and (c) the radius of greatest length, or "widest radius," which is usually found about half-way between the midrib and septum and, therefore, about 30° from the midrib. Indentations in the outline of the cross-section may be found at the septum and midrib. These represent the furrows. As the furrow at the septum is present from the beginning of ovary formation, it is referred to in this paper as the "primary furrow," while that at the midrib is referred to as the "secondary furrow."

lines with different slopes. When it was decided about how many such lines constituted the whole curve, the slope or value of k of each line was determined by the method of least squares. When these lines were plotted, they formed a continuous curve with one or more breaks at the intersections of the separate lines. The plotting of the curves was done with the advice and assistance of Professor Z. William Birnbaum of the Department of Mathematics of the University of Washington, whose kind assistance the author gratefully acknowledges. The least square values were calculated by Mr. Charles Alexander.

Since the number of points by which the slopes of the separate lines of the curves were determined was not infinite, these slopes are subject to errors of sampling, and their significance might therefore be questioned. While methods for the determination of the standard errors of k values have been devised, it was considered unnecessary to compute the standard errors in this case, for the interest here is in the general trend of the curves rather than in the exact values of k . It must be realized in considering these k

values, therefore, that they are of limited significance, but that they are sufficiently accurate to show the general trend of the curve.

To determine to what extent increase in ovary width is due to the relatively greater growth of the locule or of the wall, the ovary wall was plotted against the locule at all three radii. Also, the locule and ovary wall at the midrib were plotted against the locular region and ovary wall of both the septum and the widest radius. Again, in most cases the curve consisted of several intersecting straight lines. For comparison, corresponding intersections or breaks in the several curves are indicated by the same letter. Thus, the breaks in the curves of *giganticaerulea* are designated "B" and "C" while those in *fulva* are "H," "I" and "J."

Curves of relative growth have more significance if various places on the curve can be correlated with biological events. The development of the megaspore and megagametophyte was, therefore, studied from the slides from which the measurements had been obtained so that the stages of development would be known for ovules with midribs of various lengths.

OBSERVATIONS.—*I. hexagona* var. *giganticaerulea*.—Just after the ovary has been organized, the widest radius is the same length as the midrib and the septum is about 19 per cent shorter. Thus the ovary is circular in cross section except for the primary furrows at the septa of the three carpels (fig. 1). The midrib grows at about the same relative rate as the widest radius during the early development of the ovary, during meiosis, the development of the megagametophyte and until shortly after the polar nuclei have fused (fig. 11). During that time it grows relatively faster than the septum (fig. 12), so that a short time after the fusion of the polar nuclei (point B on both curves) the midrib and widest radius are still approximately the same length, while the septum is about 27 per cent shorter and the primary furrows are, consequently, considerably deeper (fig. 2). From that time until the capsule is partly mature, i.e., between 13 and 14 mm. in diameter (point C), the widest radius grows slightly faster than the midrib, and the septum grows faster than both. As the result of these new relative growth rates, the widest radius becomes longer than the midrib, and secondary furrows are thus produced at the midrib, while the septum becomes increasingly less short in relation to the midrib and the primary furrows become

Fig. 11-13.—Fig. 11 (above). Relative growth curve of the midrib and widest radius of *giganticaerulea*. A slight break in the curve occurs at B and a more pronounced break at C. The various stages in the development of the megagametophyte are indicated as follows: M = meiosis of megasporocyte; D = divisions of nuclei in embryo sac following meiosis; P = fusion of polar nuclei in embryo sac; S = seven-nucleate embryo sac before fertilization; F = fertilization.—Fig. 12 (center). Relative growth curve of midrib and septum of *giganticaerulea*. A break occurs at B. Symbols are the same as in figure 11.—Fig. 13 (below). less pronounced (fig. 3 and 4). The change in the slope of the line at point B is more marked in the curve of midrib and septum than in that of midrib and widest radius. In fact, as there is some scatter of points in the latter curve and as the shift in the value

Fig. 14-15.—Fig. 14 (above). Relative growth curve of midrib and septum of *fulva*. Breaks occur at points I and J. Symbols are the same as in figure 11.—Fig. 15 (below). of k after B is slight, it might be almost equally justifiable to plot the curve as a straight line from its beginning to point C. That there is probably a slight change at B is indicated by the greater change at B in figure 15, the curve of ovary wall at the midrib and ovary wall at the widest radius. When the capsule is

about 14 mm. in diameter, the widest radius is about 16 per cent longer than the midrib and the septum is about 15 per cent shorter. During the remainder of capsule development, the midrib grows relatively somewhat faster than the widest radius but still relatively more slowly than the septum. When the capsule is mature, the widest radius is only about seven per cent longer than the midrib, and the septum is about three per cent smaller; the primary and secondary furrows are both rather shallow, and the capsule is almost circular in cross section (fig. 5).

The ovary is made up of three main parts: the placenta, the locular region, and the wall. Changes in relative growth rates of the radii may be due to changes in relative growth rates of one or more of these regions. The placental region is not so important a factor as the other two since it is relatively smaller, especially during later stages of development, and also because the relative growth rates of the placental region are the same for all radii. The locular region and wall, however, are much more important.

Prior to point B in figure 11, both the midrib and widest radius are growing at the same relative rate, because the wall at the midrib is growing at the same relative rate as the wall at the widest radius (fig. 15), while the locular regions at the two radii are also growing at the same relative rate (fig. 16). Increase in the diameter of the ovary is due more to the locular region than to the wall at this time, because the locular regions are growing relatively faster than the corresponding walls (fig. 17 and 18), although relatively at the same rate in both radii.

Between the first and second breaks in the curve (points B and C), the widest radius is growing slightly faster than the midrib because the wall at the widest radius is growing faster than the wall at the midrib. Actually, the slope of that part of the curve of the walls at the midrib and widest radius is steeper than the slope of the corresponding part of the curve of the two radii. This is to be expected, since the walls make up only a part of the radii, and the locular region and placenta at the widest radius are growing at the same relative rate as the locule and placenta at the midrib. During this part of relative growth, the locular regions at both radii are growing faster than their respective walls. Since the widest wall is growing faster than the midrib wall while the locular regions are growing at the same rate, the locular region at the widest radius should not be growing so rapidly in relation to its wall as the locule at the midrib is growing in relation to its wall. That this is true can be determined by examining the slopes of the curves between points B and C in figures 17 and 18.

After the second break in the curve (point C), the midrib grows slightly faster than the widest radius, because the wall at the midrib grows somewhat faster than the wall at the widest radius, while the locular regions of both radii are growing at the same relative rate. Again the locular region grows faster than the wall in each radius, and during the final stages of

capsule development growth in diameter of the capsule is due largely to growth of the locular region. Now, however, the midrib wall is growing faster than the wall at the widest radius, so the locular region at the widest radius should be growing faster in relation to its wall than the locule at the midrib is growing in relation to the wall at the midrib.

Figures 17 and 18 corroborate this. The relation of the parts of the radii to one another are summarized in table 1.

There is only one break in the curve of midrib and septum, and this occurs at the same time as the first break in the curve of midrib and widest radius (at point B). Before that break, the midrib grows faster than the septum because the wall at the midrib grows faster than the wall at the septum (fig. 19). The two locular regions grow at the same relative rate (fig. 20). The locular region grows relatively faster than the wall in both radii (fig. 17 and 21), showing that increase in thickness of the ovary is due largely to growth of the locular region of the ovary. Since the midrib wall grows relatively faster than the wall at the septum, the slope of the curve of the locular region and wall at the septum should be steeper than that of the curve of the locule and wall at the midrib. Figures 21 and 17 show that it is steeper.

After the break (point B) and for the remainder of ovary and capsule development, the septum grows faster than the midrib, because the wall at the septum grows faster than the midrib wall and the locular and placental regions are growing at the same relative rate. Again the locular region grows relatively faster than the ovary wall at both radii. Since, now, the wall at the septum is growing relatively faster than the wall at the midrib, the latter part of the curve of midrib locule and midrib wall is steeper than the corresponding part of the curve of septum locule and septum wall.

I. fulva.—The pattern of development in this species varies considerably from that of *giganticaerulea*. The shape of the ovary just after its formation is different, for the widest radii are between five and six per cent longer than the midrib instead of the

same length, and the septum is only about thirteen per cent shorter instead of nineteen as in the other species. Consequently, the ovary in cross section is more angular, there are shallow secondary furrows, and the primary furrows are less deep (fig. 6). From that time until just about fertilization (point I), the widest radius grows relatively somewhat more rap-

Fig. 16. Relative growth curves of locule at midrib and locular region at widest radius of *giganticaerulea* and *fulva*.

idly than the midrib (fig. 13), while the septum grows noticeably more slowly (fig. 14). At fertilization the widest radius has become 18 per cent longer and the septum 29 per cent shorter than the midrib (fig. 8). The primary furrows are, therefore, very deep and the six ridges are very marked. At this point, however, the widest radius and septum both grow very rapidly relative to the midrib, and these new relative growth rates obtain until shortly after

TABLE 1. Tabular summary of the relative growth rates of the midrib and widest radius, and midrib and septum, and of the walls and locular regions of *I. hexagona* var. *giganticaerulea*. M = midrib; W = widest radius; S = septum; M Wall = ovary wall at the midrib; W Wall = ovary wall at the widest radius; S Wall = ovary wall at the septum; M Loc = locule at the midrib; W Loc = locular region of the widest radius; S Loc = locular region of the septum. The figures in parentheses are the values of *k* as found in figures 11, 12, and 15 to 21.

	Before point B	Between points B and C	After Point C
Midrib and widest radius	M = W (0.997) M Wall = W Wall (1.006) M Loc = W Loc (1.020) M Loc > M Wall (1.305) W Loc > W Wall (1.314)	M < W (1.140) M Wall < W Wall (1.1369) M Loc = W Loc (1.020) M Loc > M Wall (2.223) W Loc > W Wall (1.731)	M > W (0.900) M Wall > W Wall (0.906) M Loc = W Loc (1.020) M Loc > M Wall (2.223) W Loc > W Wall (3.403)
Midrib and septum	M > S (0.929) M Wall > S Wall (0.799) M Loc = S Loc (1.004) M Loc > M Wall (1.305) S Loc > S Wall (1.781)	M < S (1.122) M Wall < S Wall (1.664) M Loc = S Loc (1.004) M Loc > M Wall (2.223) S Loc > S Wall (1.365)	M < S (1.122) M Wall < S Wall (1.664) M Loc = S Loc (1.004) M Loc > M Wall (2.223) S Loc > S Wall (1.365)

fertilization (point J). Thus, when the capsule is about 7.5 mm. in diameter, the widest radius is about 37 per cent longer than the midrib, while the septum is only about eight per cent smaller. The ridges are more pronounced, the secondary furrows have become deeper, and the primary furrows are less deep when compared to the secondary furrows at the midrib but appear very deep because the ridges

A study of the relative importance of ovary wall and locular region in determining the relative growth rates of the radii reveals a much more complicated situation than in *giganticaerulea*. The widest radius grows slightly faster relatively than the midrib until just before fertilization (fig. 13, point I), because the wall is growing faster (fig. 15) and the locular region slightly faster (fig. 16) at the widest radius

Fig. 17-18.—Fig. 17 (left). Relative growth curves of ovary wall at midrib, and locule at midrib, of *giganticaerulea* and *fulva*.—Fig. 18 (right). Relative growth curves of ovary wall and locular region at widest radius of *giganticaerulea* and *fulva*.

are so prominent on either side of them. From then until maturity, the midrib grows relatively somewhat faster than the widest radius, while the septum grows at about the same relative rate as the midrib. The slower relative growth of the widest radius when compared with the midrib makes the ridges and secondary furrows less prominent (fig. 9). As the septum is growing at almost the same relative rate as the midrib, it is growing somewhat faster than the widest radius, so the primary furrows are also becoming less deep, since the ridges on either side of them are becoming less prominent. At maturity (fig. 10), the capsule is almost circular, for the widest radius is only about nine per cent longer than the midrib and the septum is only about nine per cent shorter. The ridges have almost disappeared, and the furrows are mere indentations.

than at the midrib. Until just after meiosis when the megagametophyte has begun to develop (point H), the locular region grows relatively much more rapidly than the wall at both radii. Since the wall at the widest radius is growing somewhat faster than the midrib wall, the slope of this part of the curve of midrib locule vs. midrib wall is steeper than the corresponding part of the curve of locular region and wall at the widest radius, as figures 17 and 18 show. From point H until just at the beginning of fertilization (point I), the widest wall grows relatively faster than the locular region at the widest radius, and the midrib wall grows at the same relative rate as, or just slightly faster than the locule at the midrib. In spite of this great shift in relative growth rates of locular regions and walls of the same radii, the relation of the midrib as a whole to the entire widest radius is

unchanged because the wall and locule at the midrib retain the same relationship to the wall and locular region at the widest radius that they had previously. The change in relative growth rates within one radius is compensated for by the change within the other radius, so that the two radii remain relatively unchanged with respect to one another.

After fertilization has begun (point I) there is another change in some of the relative growth curves and the new values obtain until after fertilization (point J). During this period of relative growth, the locular region at the widest radius continues to grow just slightly faster relatively than the locule at the midrib (fig. 16), and the wall at the widest radius continues to grow faster relative to the locular region of the widest radius and at the same relative rate as between points H and I (fig. 18). The wall at the midrib, however, now grows at a considerably slower rate relative to both the locule at the midrib (fig. 17) and the wall at the widest radius (fig. 15). The entire widest radius, therefore, grows very much faster than the midrib during this period (fig. 13).

After point J and during, therefore, almost all capsule development, the wall at the widest radius slows up greatly relative to the midrib wall and actually grows a little more slowly than the wall at the midrib (fig. 15). It is because of this change in the relative growth rates of the walls that the midrib grows slightly faster than the widest radius during the maturity of the capsule. During this period the locular regions of both radii are growing relatively faster than their respective walls. The locule at the midrib grows relatively faster than the wall at the midrib (fig. 17), which in turn grows slightly faster relative to the wall at the widest radius. The locular region at the widest radius is growing slightly faster than the locule at the midrib. Therefore, the curve of the locular region and wall at the widest radius should be somewhat steeper than that of the locule and wall at the midrib. Figures 17 and 18 show that this is so.

Until just before fertilization (point I), the midrib grows somewhat faster in relation to the septum (fig. 14) because the wall at the midrib grows somewhat faster than the wall at the septum (fig. 19), while the locular regions at the two radii grow at the same relative rate (fig. 20). Until after meiosis (point H), the locule at the midrib grows relatively faster than the midrib wall, and the locular region of the septum grows relatively faster than the wall at the septum. Since the wall at the midrib is growing slightly faster than the wall at the septum, the curve of locular region and wall at the septum should be slightly steeper than that of the locule and wall at the midrib before point H. A comparison of figures 17 and 21 shows that this is so. Between points H and I, the locular region at the septum grows at the same relative rate as the wall at the septum, while the midrib wall now grows slightly faster than the locule. The shifts at point H in the relative growth rates of locular regions and walls of the same radii do not affect the relative growth rates of the entire

Fig. 19. Relative growth curves of ovary wall at midrib and ovary wall at septum of *giganticaerulea* and *fulva*.

radii, since the locular region and wall of one radius still grow at the same relative rates as the corresponding regions of the other radius. The change at point H is a very interesting one. Before that point, the locular regions of both radii grow considerably faster than the walls at the same radii, but since the locular region at the septum grows slightly faster in

Fig. 20. Relative growth curves of locule at midrib and locular region at septum of *giganticaerulea* and *fulva*.

relation to its wall than the locule at the midrib does in relation to its wall, and since the locular regions grow at the same rate in relation to each other, the midrib wall grows slightly faster relative to the septum wall and, therefore, the midrib as a whole grows slightly faster than the septum as a whole. After point H, however, and until point I, the locular regions cease to grow faster relative to their walls. The locular region at the septum is now growing at the same rate as both the septum wall and the locule at

spect to relative growth is: septum wall, locular regions at septum and midrib, and midrib wall.

During most of capsule development (after point J), the locule at the midrib grows faster than the midrib wall, maintaining the same relative growth rate that was established at point I (fig. 17). The relative growth rates of the regions of the septum are now changed, however, for after point J the locular region grows faster than the wall (fig. 21). Since the midrib locule in relation to its wall grows somewhat faster than does the locular region at the septum in relation to the septum wall, the septum wall grows slightly faster than the midrib wall. In view of the fact that the two locular regions and placental regions are growing at the same rate, the somewhat faster growth of the septum wall relative to the midrib wall has but slight effect on the relative growth rate of the midrib and septum as a whole.

The relative growth rates in *fulva* are tabulated in table 2.

DISCUSSION.—The differences in form of the two species are due first to differences in initial shape and second to differences in relative growth rates. Initially, the ovary of *fulva* is slightly angular and has six small but definite ridges, while that of *giganticaerulea* is circular except for the three primary furrows. In the earlier stages of ovule development, the widest radius grows somewhat faster in *fulva* than the midrib but at the same relative rate as the midrib in *giganticaerulea*. During the same period the septum grows somewhat more slowly than the midrib in both species. Therefore, the ridges become increasingly more prominent in *fulva* but do not become prominent in the other species, while the primary furrows become deeper in both species but more so in *fulva*.

Coincident with fertilization, the widest radius and septum grow much faster in relation to the midrib in *fulva* than in *giganticaerulea*. These rates do not extend much past fertilization, but they increase greatly the ridged character of the *fulva* ovary during that period.

In the development of the capsule after fertilization, the midrib grows slightly faster than the widest radius in *fulva*, but in the other species it grows slightly more slowly until the capsule is partly formed and then slightly faster. In *fulva* the septum and midrib grow at almost the same rate during the entire development of the capsule, while the septum grows relatively faster in *giganticaerulea*. Thus, changes in growth rates continually diminish the difference between the two species which was so striking at about the time of fertilization.

It is interesting to note that in both species changes in the relative growth rates of two radii are due entirely to changes in the relative growth rates of their walls. In *giganticaerulea* the locular region at the widest radius grows continually at about the same relative rate as the locule at the midrib, while in *fulva* it grows just slightly faster throughout. In both species the locular region at the septum grows at the same relative rate as the locule at the midrib.

Fig. 21. Relative growth curves of ovary wall and locular region at the septum of *giganticaerulea* and *fulva*.

the midrib. Since, however, the wall at the midrib grows somewhat faster than the locule at the midrib and, therefore, than the locular region and wall at the septum, the same relation is maintained between the midrib wall and septum wall and between the midrib and septum that existed before point H. Between points I and J, the septum grows very rapidly in relation to the midrib (fig. 14) because the septum wall grows very fast in relation to the midrib wall (fig. 19), while the locular region at the septum grows at the same relative rate as the locule at the midrib (fig. 20). The wall at the septum grows much faster than the locular region (fig. 21). Since the locular regions at the midrib and septum grow at the same relative rate, while the wall at the septum grows faster than the locular region at the septum, the wall at the septum must grow faster than the locule at the midrib, which in turn grows faster than the midrib wall. During this period (from just before until shortly after fertilization), the order with re-

TABLE 2. Tabular summary of the relative growth rates of the midrib and widest radius, and midrib and septum, and of the walls and locular regions of *I. fulva*. The symbols are the same as for table 1. The figures in parentheses are the values of *k* as found in figures 13, 14, and 15 to 21.

The relative growth rates of any two locular regions do not change from the beginning of ovule formation to the end of capsule development. Therefore, all changes must be due to changes in the relative growth rates of the ovary walls. The relative growth rates of the locular region and the wall of the same radius may change, but the locular region of one radius does not change in relation to the locular region of another radius.

In view of recent studies on hormones and fruit development, one is tempted to hypothesize a hormonal control of these relative growth rates. While such a suggestion seems very probable, the author has no experimental evidence to substantiate it.

SUMMARY

Various radii of cross sections of developing capsules of *Iris fulva* and *I. hexagona* var. *giganticaerulea* are compared. Although corresponding capsule dimensions of these two species are not very different

in the very early developmental stages and at maturity, they differ considerably in the intervening stages, since *fulva* has a much more ridged and furrowed ovary than *giganticaerulea*.

By means of logarithmic plots of one radius against another at different developmental stages, an analysis of the relative growth rates of the radii has been made. The linear relationships obtained are interpreted in the light of Huxley's heterogenic growth formula. The differences in the capsule development of the two species are described in terms of differences in the relative growth rates of their radii.

Similar logarithmic plots of the locular regions of two radii and of the ovary walls of the same radii show that differences in the relative growth rates of the radii are due chiefly to differences in the relative growth rates of the ovary walls at those radii.

SOME RECENTLY COLLECTED SPECIMENS OF SCHIEDEA
(CARYOPHYLLACEAE) AND OF MEXICAN
COMPOSITAE ¹

Earl Edward Sherff

SCHIEDEA haleakalensis Degener & Sherff, sp. nov.—Frutex glaber, circ. 6 dm. altus; caulibus multis, subadsurgentibus et inter se laxè innexis, gracilibus, stramineis, fragilibus, ligneis (nodis tumidis, internodiis circ. 2 cm. longis); ramis foliosis, viridibus, saepe praecipue ad nodos subpurpurascenscentibus. Folia 4–8 cm. longa et 2–3 mm. lata, carnosa, pallida, subflaccida, 1-nervia, linearia, nitida, apice acuta, basi sessilia subamplexicaulique, submarcescentia, integra, marginibus incrassata, nervo mediano supra profunde sulcata infra prominenter lata crassaque. Flores numerosi, in paniculis erectis 3–5 cm. longis et 2 cm. latis dispositi; pedicellis gracilibus, puberulentis, circ. 4 mm. longis, basi 2-bracteolatis. Sepala 3 mm. longa, viridia, ovata, subobtusa, glabrata. Staminodia sepalis paulo breviora, subalba, linearia, apice obtusa, basim versus tumida subflavidaque. Stamina circ. 4 mm. longa, ea cum sepalis alternantia quam altera paulo breviora; filamentis gracilibus, albis; antheris pallido-flavis. Ovarium pallido-viride, glabrum, subglobosum; stylis 3. Capsula circ. 4 mm. longa. Semina compressa, orbicularia, 0.7 mm. lata, fusco-griseo-brunnea, colore hebetia, implicate profundeque stellato-sulculata.

Glabrous, about 6 dm. tall, shrub with many somewhat assurgent and loosely intertwined slender stramineous brittle woody stems having about 2 cm. long internodes and swollen nodes; leafy twigs green, often shaded with purple, especially at nodes. Leaves 4–8 cm. long and 2–3 mm. wide, fleshy, pale, somewhat flaccid, 1-nerved, linear, shiny, acute at apex, slightly clasping at sessile base, with midrib deeply sulcate above and prominently wide and thick below, entire with thickened margin, somewhat marcescent. Flowers numerous, on about 4 mm. long slender puberulent pedicels bibracteolate at base to form 3–5 cm. long and 2 cm. wide erect panicles. Calyx with 3 mm. long green ovate somewhat obtuse glabrate sepals. Staminodia slightly shorter than sepals, whitish, linear, with obtuse apex; swollen and yellowish near base. Stamens about 4 mm. long, those alternating with sepals slightly shorter than others; filaments slender, white; anthers pale yellow. Ovary pale green, glabrous, subspherical; styles 3. Capsule about 4 mm. long. Seeds compressed, orbicular, 0.7 mm. wide, dark grayish-brown, dull, intricately and deeply stellate-grooved.

Specimens examined: *Otto Degener, Emilio Ordoñez, & Felix C. Salucop* 12,695, Mt. Haleakala cliffs on west side of Kaupo Gap, eastern Maui, Hawaiian Islands, August 11, 1939 (type, N. Y. Bot. Gard.).

The type material, of which several specimens are being distributed to herbaria, was found growing

beyond the reach of wild goats on the arid cliffs that extend from Mt. Haleakala southeast along the western side of Kaupo Gap, on the Island of Maui. It is named, not for the great rift-valley known as Haleakala Crater, but for the mountain on which it grows. The species is related to *S. kealiae* Caum & Hosaka, of the dry cliffs about Kawaihapai, on the Island of Oahu.

BIDENS HETEROSPERMA A. Gray, Pl. Wright, 2: 90. 1853. In my monograph on the genus *Bidens* (Field Mus. Bot. Ser. 16: 381. 1937), this species was said to grow as far south as the Territory of Baja California and the states of Sonora and Chihuahua, Mexico. The range is now seen to be extended into the State of Sinaloa, Mexico, by the following two collections: *Howard Scott Gentry* 6,428, steep, moist canyon slope with mixed dominants, pine forest area, alt. $\pm 6,000$ –7,000 feet, Ocurahui, Sierra Surotato, September 1–10, 1941 (Field); *Gentry* 6,469, northern exposure, steep, moist canyon slope under mixed dominants, pine-oak forest, alt. $\pm 4,000$ –5,000 feet, Quebrada de Mansana, Sierra Surotato, September 10–14, 1941 (Field).

COREOPSIS CONGREGATA Blake, Jour. Wash. Acad. Sci. 19: 275. 1929.—Hitherto, this species has been known only from the type collection, obtained by the late Miss Ynes Mexia, no. 445. She had described it as common at altitude of 1,200 meters, growing in masses, in damp places in openings in oak and pine forests, trail from El Batel to Pica de Aguila, Sierra Madre, State of Sinaloa, Mexico, November 14, 1925. Recently additional material has been collected by Mr. Gentry, his no. 6,326, likewise in the State of Sinaloa. The label in the Herbarium of Field Museum bears the data: on moist boulders; rays orange with yellow tips; on steep, moist, shady canyon slope with mixed dominants; Ocurahui, Sierra Surotato, September 1–10, 1941.

DAHLIA Gentryi sp. nov.—Herba perennis, erecta, gracilis, pauciter ramosa, forsitan 5–10 dm. alta, radicibus non visis; caule plus minusve tereti, glabro, numerosè sulcato, infra circ. 2.5 supra ± 1.5 mm. crasso, internodiis 6–9 cm. longis. Folia opposita, graciliter petiolata petiolo sparsissime minutissimeque piloso usque ad 5.5 cm. longo, petiolo adjecto circ. 1.3–1.5 dm. longa, lamina bi- vel inferne tripinnata, rhachi gracillima ± 0.5 mm. lata, segmentis primariis 3 vel 5, gracillime petiolulatis petiolulo 1–3.5 cm. longo; ultimis saepe ternis, anguste ovatis vel rarius lanceolatis, 2–4.5 cm. longis et 0.8–2.4 cm. latis, apice plus minusve acuminatis basi late cuneatis vel oblique rotundatis, margine hispidulo-ciliato acriter 1–6-serratis pro utroque latere, membranaceis, faciebus secundum venulas moderate (et supra minutissime) alibi sparsissime adpresso-hispidulis, in-

¹ Received for publication January 20, 1942.

fra pallidioribus et eleganter reticulato-venulatis. Capitula perpauca (± 3), gracillime pedunculata pedunculo ± 1.3 dm. longo, radiata, ad anthesin ± 3.5 cm. lata et ± 1.2 cm. alta. Involucri bracteae exteriores circ. 5 vel 6, ad anthesin reflexae, subcarnosae, nunc oblongae vel lineari-oblongae nunc lanceolato-ovatae, glabratae, apice subacutae, 7–9 mm. longae et 2–3 mm. latae; interiores erectae, ovato-oblongae, apice rotundato-obtusae, ± 12 mm. longae et ± 5 mm. latae. Flores ligulati ± 8 , flavi; ligula obovata apice irregulariter 2- vel 3-dentata, ± 1 cm. longa. Flores disci plus minusve flavi. Ovaria plana, circumambitu orthogonio-oblonga vel -cuneata, apice calva, alibi glabra vel marginibus perpauciter setulosa. Achaenia non visa.

Perennial herb, erect, slender, sparingly branched, perhaps 5–10 dm. tall, roots not seen; stem more or less terete, glabrous, multisulcate, infernally about 2.5 mm., supernally ± 1.5 mm., thick, internodes 6–9 cm. long. Leaves opposite, slenderly petiolate (petiole very sparsely and very minutely pilose, up to 5.5 cm. long), about 1.3–1.5 dm. long including the petiole; blade bi- or infernally tripinnate, rhachis very slender and ± 0.5 mm. wide, the 3 or 5 primary segments very slenderly petiolulate with a petiolule 1–3.5 cm. long; ultimate segments often in threes, narrowly ovate or more rarely lanceolate, 2–4.5 cm. long and 0.8–2.4 cm. wide, at apex more or less acuminate, at base cuneate or obliquely rounded, at margin hispidulous-ciliate and with 1–6 serratures to each side, membranaceous, along the small veins of both faces moderately (and on upper face most minutely) elsewhere very sparsely appressed-hispidulous, infernally rather pallid and neatly reticulate-

venulate. Capitula very few (± 3), pedunculate (peduncle very slender and ± 1.3 dm. long), radiate, at anthesis ± 3.5 cm. wide and ± 1.2 cm. tall. External involucral bracts about 5 or 6, at anthesis reflexed, somewhat fleshy, now oblong or linear-oblong now lanceolate-ovate, glabrate, at apex subacute, 7–9 mm. long and 2–3 mm. wide; interior bracts erect, ovate-oblong, at apex rounded-obtuse, ± 12 mm. long and ± 5 mm. wide. Ligulate florets ± 8 , yellow; ligule obovate, at apex irregularly 2- or 3-dentate, ± 1 cm. long. Disc florets more or less yellow. Ovaries flat, in outline rectangular-oblong or -cuneate, at apex bald, elsewhere glabrous or at margins very sparingly setulose. Achenes not seen.

Specimens examined: *Gentry* 6,275, an openly branched perennial herb, on open lava pile, steep, moist, shady canyon slope with mixed dominants, in pine-forest area, alt. 6,000–7,000 feet, Ocurahui, Sierra Surotato, State of Sinaloa, Mexico, September 1–10, 1941 (type, Herb. Field Museum Nat. Hist.).

A species with ultimate leaf-segments somewhat similar to those of *Dahlia Merckii* Lehm. In that species, however, the leaves are merely once-pinnate, the peduncles mostly 2–4 times as long, the flowering heads much larger, the ligules lavender or rosaceous, etc. The type, together with the preceding and several other specimens collected by Mr. Gentry in Sinaloa, had been very kindly turned over to me by the Curator of the Herbarium at Field Museum of Natural History, Paul Carpenter Standley.

FIELD MUSEUM OF NATURAL HISTORY,

THE FLORAL MORPHOLOGY OF THE CARYOPHYLLACEAE¹

Betty Flanders Thomson

THE CARYOPHYLLACEAE as a group include forms with small, simple flowers, such as *Sagina*, and others having large showy flowers such as *Dianthus* and *Lychnis*. Within the family a series can be arranged showing intergradations from a pentacyclic flower with many ovules in a completely septate ovary to a tricyclic flower with a simple perianth, one stamen whorl, and a unilocular, one-seeded ovary. This is usually, though not always, interpreted as a descending series, going in evolutionary sequence from the less reduced to the smaller forms. The present study was undertaken in order to analyze the vascular anatomy of representative flowers within this group and to interpret the bearing of data thus obtained on the relationships within the family and with other

groups. Such work should also throw light on the fundamental nature of the flower.

In the study of floral morphology emphasis was early laid on internal anatomy, especially the course of the vascular bundles, in a classic paper by van Tieghem in 1867. Further studies in this field were made by Henslow (1888 and 1890), Olbers (1895), Wester (1899), and Grélot (1897), who summarized the work on floral anatomy to that date.

The accumulated facts were interpreted specifically in terms of the anatomy of the leafy shoot by Eames and MacDaniels in 1925. This was further elaborated in detail by Eames in 1931.

Saunders has made a wide study of vascular patterns in flowers. Her work has been brought together into two volumes (1937 and 1939) which are dominated by the concept of carpel polymorphism but contain much detailed information.

These and other anatomical studies support the concept of the flower as a reduced axis beset with appendages which are in some manner homologous with foliage leaves and sporophylls. Other concepts, such

¹ Received for publication February 2, 1942.

I should like to express my thanks to Prof. Edwin B. Matzke for his very helpful suggestions and criticisms during the course of this work.

as H. H. Thomas' derivation of the carpel from concrescent cupules, or J. M. Thompson's sporogenous axis, seem to disregard the structural likeness of floral parts to foliar organs, or to dismiss it as not highly significant.

Most workers agree that the primitive flower consists of many parts separately attached and spirally arranged upon a somewhat elongated receptacle; that cyclic arrangement and adhesion between cycles follows upon reduction in the number of members in a whorl and reduction in length of the axis or receptacle; that cohesion within a whorl is derived from the separate state. The vascular skeleton of plants is considered to be more resistant to change than other structures. It may or may not follow the fusions, reductions, or elaborations that the softer tissues undergo. For example, in the family Crassulaceae, tribe Kalanchoideae, the level of insertion of filament tissues upon the corolla varies from species to species, but the distance for which the vascular traces for petal and stamen are fused remains constant within the genus (Tillson, 1940).

LITERATURE ON THE CARYOPHYLLACEAE.—Several studies of floral ontogeny of the Caryophyllaceae have been published. The earliest is that of Payer (1857), who described the five whorls of floral parts as arising in acropetal sequence. Rohrbach (1868) found the same situation in *Silene*. Lister (1883) investigated carpel development in several species. She found that the early development of flowers with small incompletely septate ovaries is essentially the same as that of those having larger capsules with complete septa; that differences in form of mature capsules are due to differences in growth rates of ovary wall, septa, and central column. Schaefer (1890) studied other species with special attention to the rôle of the axis in ovary construction. Middleton (1914) followed the organogeny of *Saponaria officinalis*.

The vascular anatomy of various species of the Caryophyllaceae has been described by van Tieghem (1867), Henslow (1888 and 1890), Olbers (1895), Wester (1899), and Saunders (1925, 1932, and 1937). These accounts do not take into consideration the significance of the anatomy for relationships nor for floral morphology in general.

Pratt (1932) studied the floral anatomy of *Silene maritima* and concluded that incomplete development of stamens and petals is not due to anatomical defects of the vascular bundles. Dickson (1936) in a study of the Primulaceae described the vascular plans of *Melandrium album* and *Sagina procumbens*, and Dawson (1936) that of *Silene noctiflora* for purposes of comparison with the Polemoniaceae.

The present concept of the Centrospermae in the sense of Pax and Hoffmann (1934) as a natural line dates from a paper by Bentham in 1862. Bentham and Hooker (1862) listed the family among the Thalamiflorae, which starts with the Ranales. They did not specify phylogenetic relationships, but the sequence of genera implies that the family is a line of reduction. Wernham (1911) placed the Caryophylla-

ceae close to the Ranales and considered them the point of departure for the Primulaceae as well as for the more reduced Centrospermae families. Bessey (1915) arranged these families in a similar fashion, basing his ideas definitely on the strobiloid nature of the flower. Hutchinson (1926) regarded the Caryophyllaceae as derived from the Ranales through the Saxifragales and as the base from which arose many herbaceous lines, such as Centrospermae, Geraniales, and Primulales.

Eichler (1875) considered that the Centrospermae are a line of elaboration from the Polygonaceae and thought that the origin of the Caryophyllaceae is to be found among the Phytolaccaceae. The complete flowered Caryophyllaceae arose from a form like *Phytolacca* by conversion of the outer stamen whorl to petals and of the outer carpel whorl to stamens; from this the family shows a line of reduction. The same origin was proposed by Pax (1893 and 1927); by Bitzek (1928), who regarded the family as showing elaboration from a simple flower; by Lüders (1907), who saw reduction by abortion of a stamen whorl in three-whorled, and elaboration by dedoublement of the same stamen whorl in five-whorled members; and by Rendle (1938), who presented essentially the same views as Eichler.

Möbius (Warming, 1929) considers the Alsineae to be primitive within the family, with Paronychieae a series of reduction thence and Silenoideae elaborated with respect to insect pollination. Troll (1928) considers the family to be a line of reduction.

Coulter and Chamberlain (1903) regarded the Caryophyllaceae as the highest family of the Centrospermae. This entire line seemed to them unrelated to the Ranales and lines stemming thence. Pax and Hoffman (1934) consider that the Chenopod-Amaranth group gave rise to Phytolaccaceae and Caryophyllaceae as parallel lines. They consider the genera of the latter to show a sequence of elaboration from simple to large and complete flowers. Wettstein (1935) also upholds this point of view.

Much discussion has centered about the break in alternation sequence of stamen and carpel whorls in the Caryophyllaceae. Čelakovský (1875) discussed the various theories presented up to that time to explain this irregularity; he concluded that obdiplostemony in the androecium is secondary in this family and that so far as the gynoecium is concerned no single explanation fits all the cases. Schumann (1889) regarded the stamens in this family as really diplostemonous; contact during formation seemed to him to be the factor which determines the position of carpels. Stroebel (1925) reported that successive floral whorls are formed in acropetal sequence; that obdiplostemony arises by an increase in the calyx sectors, either by simple enlargement of primordia at an early stage, or by that in combination with a higher level of insertion of anteseptalous stamens; and that petal sectors show a corresponding tendency to reduction. Saunders (1935) postulates that in isomerous six-whorled flowers ($G=5 \text{ \& } 5$) in which midrib traces for all parts arise directly from the

stele, a "state of congestion" is set up after the formation of the second stamen whorl. Consequently the "outer" carpels (loculi) stand on petal radii unless some structural feature allows more space for the developing carpels; such features are a gynophore or the fusion of the basal parts of stamens with their subtending perianth parts.

Glück (1919) studied the morphology of floral leaves and concluded that sepals and petals are derived from foliage leaves, and stamens from petals. Homologues of the stipules of vegetative leaves can be seen in thin or membranous margins of sepals, in lateral wings on the petals of *Lychnis*, in glands at the bases of stamens as in the tribe Alsineae. Mattfeld (1938) saw in this view a solution of the problem of obdiplostemony in that if glands are stipules of antepetalous stamens, then petals are stipules of antepetalous stamens, which bear no such abaxial glands, and there are thus only two whorls between carpels and sepals. Arber (1939) showed by anatomical investigation that coronal teeth of *Lychnis* are simply dorsal invaginations and not ligules or enations or sutural ridges; that the lateral wings may be stipules as well as not; that Mattfeld's interpretation of petals as stipules is unsound. She pointed out that in the Caryophyllaceae petal plus stamen may "count" as one whorl or as two in the alternation sequence which ends with the formation of carpels.

The well-known variability in petal and stamen whorls of *Stellaria media* has been carefully studied by two investigators. Kraft (1917) reported that the number of these members can be controlled experimentally by varying the external conditions. Reduced flowers obtained thus reproduced the floral diagrams of typically oligomeric species. Reduction by abortion of members was observed in the floral ontogeny of some species. He concluded that simpler members of the family are reduced; that the most primitive forms in the family are those in the tribe Alsineae with complete flowers, the Sileneae showing such entomophilous adaptations as dichogamy and sexual dimorphism. Matzke has also studied variation in *S. media*, with special reference to symmetry. He found that extra or missing members are fairly well fixed in their location with reference to sepals (1929); that nutrition as influenced by variegation and by removal of flowers after anthesis plays an important part in determining the number of stamens formed (1930); that most variations which occur result in bilateral or radial symmetry of the individual flower (1932).

Vivian (1940) studied the structure and symmetry of flowers of *Sagina procumbens*. He found considerable regularity in the sequence of disappearance of the stamens.

MATERIALS AND METHODS.—Flowers in anthesis were preserved in a formalin-acetic acid-alcohol mixture, embedded in paraffin, sectioned serially at ten to fifteen microns, and stained in safranin and fast green. Complete series were studied, both transverse and longitudinal. Flowers were also cleared in 70 per cent lactic acid and studied whole. Some mate-

rial of buds and young flowers was presented to the writer already embedded in paraffin by Professor T. E. Hazen.

The vascular traces of flowers vary from substantial strands similar in size and composition to those of foliage leaves, as found in sepals, petals, and carpel walls, to procambial strands detectable only as elongated cells with small diameter and densely staining contents, such as those comprising the bases of stamen traces. Stamen traces are often faint and indefinite where they leave the stele, becoming stronger and showing mature xylem elements above.

In this paper the term *median lateral* carpellary traces refers to those which stand in the carpel wall at the ends of the septa. By *stelar internode* is meant a longitudinal segment of stele between the levels of departure of successive whorls of traces, uncomplicated by gaps or departing traces. The term *gynophore* is applied only to a stipe upon which the ovary is elevated. The term *perigyny* is used in quotation marks because the condition in this family clearly arises by the fusion of superposed whorls, and not by an up-growth of the torus.

The genus and species names used are those given by Gray's Manual (1908), or in the case of cultivated plants by Bailey (1938).

GENERAL MORPHOLOGY.—The flower of the Caryophyllaceae is typically hypogynous, actinomorphic, pentacyclic, and pentamerous or occasionally tetramerous.

The calyx is well developed, with sepals free in the tribe Alsineae, united into a tube in the Sileneae. In many members of the last tribe the lateral veins of adjacent sepals arise fused in pairs and stand on the commissure line; they are, therefore, often termed "commissurals." The commissurals may split into component parts near the base of the calyx, just below the sinuses, or not at all. Branches from the commissurals may or may not anastomose with those from the midrib.

Petals in the Sileneae are often differentiated into claw and limb, and often bear a corona or paracorolla at the juncture of these. In the other tribe the petals may be cleft or entire, isomerous with the sepals, or fewer in number, or altogether lacking.

Stamens in the Sileneae regularly form two complete whorls, of which the antepetalous set is pushed out against the petals in their upper reaches because of spatial relations. In the other tribe the stamen number may be reduced, either by disappearance of the complete antepetalous whorl or by abortion of part of a whorl, or both. The filament bases are frequently united into a very short tube and frequently adhere to the petal bases even above the level of separation of petals from each other.

Nectar tissue often forms a ring on the adaxial face of the tube formed by the united filament bases. In the Sileneae the glandular tissue is limited to this region. In the Alsineae this ring is somewhat thinner in the radial dimension, but glandular tissue may also form a collar around the base of each antepetalous stamen, extending below the level at which

the filaments become free, and often project in a lump on the abaxial side.

The syncarpous pistil is composed of five to two carpels with axile placentation, frequently, but as Goebel (1933, p. 1912) points out, falsely described as "free-central." Flowers up to the embryo sac stage of most species examined show at least the remains of complete septa. In later stages the septa, especially in the center and upper regions of the ovary, become delicate and fragmentary and may disappear entirely. Near the top of the ovary the partitions do not meet in the center, as though each carpel had a split or a hole in its adaxial face near the top. Septation is complete again below the bases of the separate styles. Ovules are attached to the placenta in double rows opposite the dorsal veins.

In the Alsineae species occur which show a reduction in the number of ovules and in the length of the placental column. In some of these the septa extend only part way up into the ovary cavity, with the result that the ovary is unilocular above. However, the placentation is not truly free-central even in these cases (Lister, 1883).

TRIBE SILENEAE.—*Dianthus* K5, C5, A5 & 5, G2.
—Four species were studied: *D. barbatus*, *D. chinensis*, *D. plumarius*, and *D. armeria*.

The pedicel is traversed by a complete vascular cylinder.

At the base of the flower a whorl of ten traces departs from the central cylinder. Of these, five small, simple strands become sepal midribs; each of the alternate set of large traces splits periclinally near the base; the resulting abaxial strand, a calyx commissural, immediately branches freely and enters the calyx tube; the adaxial strand becomes a petal midrib (fig. 3A-D). In *D. plumarius* petal traces arise from the same ribs on the stele as calyx commissurals, but the two are not really fused—that is, serial cross sections from the base upward show that the ribs from which the calyx commissurals depart are not completely retracted into the stelar cylinder until above the departure of the stamen traces (cf. fig. 18). In *D. armeria* the sepal midrib whorl is slightly but definitely lower in origin than the commissural (fig. 4); in the other species all ten traces depart as a single whorl. These traces are practically unbranched above the base and do not anastomose. There is a stelar internode above the departure of perianth traces.

Stamen traces arise independently from the stele. In *D. barbatus*, *D. chinensis*, and *D. plumarius*, the antesepalous whorl arises slightly below the antepetalous; in *D. armeria* both arise at the same level. In all species the antesepalous stand slightly farther out in the receptacle than the others (fig. 3F). Another stelar internode follows the departure of stamen traces.

Two dorsal carpellary strands arise at the base of the gynophore in *D. barbatus* (fig. 3F-K) and *D. chinensis*, just a short distance below the median laterals in *D. armeria* and *D. plumarius*. In *D. barba-*

tus, *D. plumarius*, and *D. chinensis*, forms with large capsules, an extra set of traces for the ovary wall arises between dorsals and true median laterals (fig. 3G). These extra strands die out at the top of the ovary. Dorsal traces enter the styles.

The true median laterals arise just below the loculi and traverse the ovary wall, one at each end of the septum. These traces fork at the base of the styles, and one branch from each lateral enters each style (fig. 3L-O), except in the case of *D. armeria*, where the laterals die out just after forking.

The remaining central vascular cylinder is traversed by a large central core of xylem (fig. 1-4). Higher up in the placenta this core becomes smaller and forms a band at right angles to the plane of the septum; in some sections it appears split along its long axis. It dies out at the topmost ovule traces. The pith disappears between a point just above the insertion of stamen traces and the level where median laterals depart.

Above the attachment of the ovules the septa withdraw from the center, so that a small part of the top of the ovary is incompletely septate. In *D. armeria* and *D. barbatus* the free ends of the septa are bilobed (fig. 3M). This, with the forking of the median laterals, suggests that the two carpels are incompletely fused at the top.

Henslow (1890) stated that in *D. barbatus* the petal traces arise directly from the stele, and each soon gives rise to a stamen trace. The observations of Olbers (1895) agree with those described in the present paper; she described also *D. deltoidea*, in which traces for both perianth whorls arise as a single complete ring which segments into its component parts. Wester (1899) gives figures of the ovary of this species showing the median laterals double at the top but apparently not entering the styles.

Gypsophila K 5, C 5, A 5 & 5, G 2.—Three species were studied: *G. muralis*, *G. elegans*, and an unidentified species, possibly *G. paniculata*, received already in paraffin.

The vascular tissue in the pedicel forms a complete cylinder.

At the base of the flower a whorl of ten traces departs. Of these strands, one set of five become sepal midribs which branch to varying extents. Each member of the alternate set of five immediately splits anticlinally into three strands, of which the median and by far the largest becomes a petal trace, and the others extend into adjacent sepals as lateral veins (fig. 5). In *G. muralis*, a very small flower, sepal laterals separate from only two or three of the petal traces, although all sepal laterals which extend to the base of the calyx arise thus. In *G. elegans* and *G.* species sepal laterals separate from all petal traces. In this genus the sepal margins are fused, but the vascular systems of the calyx segments are separate and independent except at their origin. In the fresh flower each segment consists of a central green strip bearing a network of veins, and a colorless margin.

Above the gaps from the perianth traces a single whorl of ten stamen traces arises independently from the stele (fig. 5, 7).

Above the stamen traces a pair of dorsal carpellaries arises. A pair of median lateral carpellary traces arises just below the bases of the ovary loculi; these consist of a single small bundle at each end of the septum. The ovary wall is supplied also by minor branches from these four strands and from the central remnant. The dorsal bundles extend into the styles; the median laterals die out at the base of the styles, forking dichotomously just before they do so in the case of *Gypsophila* sp. and *G. elegans*.

The tissue between the stamen bases and bottom of carpel loculi may be elongated into a gynophore as in *G. muralis* (fig. 7), or not, as in *G. elegans* (fig. 5), where the dorsal carpellaries leave the stele below the level of the glandular ring at the stamen bases.

After the carpel walls have been supplied, the central vascular remnant is a complete hollow cylinder which soon domes over and continues as a central mass of ovule traces. In *Gypsophila* sp. and *G. muralis* this placental mass has a central core of a few xylem elements. The downward connection of these is obscure, but seems to be to the inner edge of the vascular cylinder before the pith disappears. The placental septum separates near the topmost ovules into two lobes, as in the case of *Dianthus*. The placental vascular strand divides as the septa draw apart (fig. 6).

Saponaria K 5, C 5, A 5 & 5, G 2.—Two species were studied: *S. calabrica* and an unidentified species received in paraffin.

The stele in the pedicel is a complete cylinder.

The calyx traces depart as a whorl of ten, of which those on the midrib radii become free slightly below the others. In *S. calabrica* these whorls are markedly reflexed at their origin, following the form of the saccate base of the calyx (fig. 8).

Just above the calyx traces and slightly fused with them at the base arises another whorl of ten traces. The five of these standing on sepal radii are simple stamen traces; the alternate five soon split periclinally, each outer branch becoming a petal midrib, each inner a stamen trace.

The stele closes above these traces and the central pith soon domes over. Dorsal carpellary strands separate from the stele at the base of a gynophore in *S. calabrica*, just below the loculi in *Saponaria* sp. Both species have a single pair of unbranched median laterals, one at each end of the septum. These seem to fork at the top of the loculi before they die out, but the material at hand is young and the exact limits of traces are hard to determine. The placental vascular supply is single and central in the lower region, and splits into two at the top in *S. calabrica*.

In *Saponaria* sp. the entire placental column is ovuliferous; *S. calabrica* bears only two tiers of ovules about halfway up the loculi. The ovary is completely septate in both species, at least in the relatively young material available.

In *S. officinalis*, as described by Olbers (1895), the calyx traces are reflexed at the base and the stamen traces arise in two successive whorls, the antesealous lower. Saunders (1932) mentions the splitting of the placental strand above the level of the ovules in this species. Middleton (1914) stated that the ovary wall is lined with an epidermis which forms a definite absciss layer and thus actually cuts off the septa from the ovary wall.

Lychnis K 5, C 5, A 5 & 5, G 5.—Six species were studied: *L. alba*, *L. dioica*, *L. chalcadonica*, *L. flos-jovis*, *L. coeli-rosa*, and *L. coronaria*.

The vascular supply in the pedicel varies, being a practically complete cylinder in *L. flos-jovis* and *L. coeli-rosa*, a ring of five strands in *L. chalcadonica*, and a ring of eight or ten strands in *L. alba* and *L. dioica*.

The calyx is supplied by a whorl of ten traces. In *L. chalcadonica*, *L. coeli-rosa* (fig. 9), and *L. coronaria* (fig. 10) the traces on the sepal midrib radii arise slightly but definitely lower than the commissurals. In all species the midrib strands are relatively simple, but in *L. alba* ♀, *L. dioica* ♀, and *L. coronaria* the commissurals are larger and branch extensively near their origin. In *L. coeli-rosa* and *L. chalcadonica* the sepal traces are strongly reflexed in the base of the flower.

Petal traces arise in close conjunction with the calyx commissurals. They may arise from the same stelar rib as the commissurals, as in most species, or be slightly fused with them as in *L. dioica* ♂ and *L. alba* ♂ (fig. 11). In *L. coronaria* they arise practically independently (fig. 10).

Stamen traces arise independently from the stele, barely so in *L. alba* and *L. dioica*, markedly so in the other species. Staminodia in the pistillate flowers of *L. alba* and *L. dioica* show as small stumps or pegs, each with a short but distinct vascular trace (fig. 13). The antesealous traces arise slightly lower than antepetalous in *L. flos-jovis* (fig. 12), *L. alba* ♀, *L. dioica* ♀ (fig. 13), and *L. coronaria* (fig. 10); in the others there is no discernible difference. In all cases these strands lie in a single ring as soon as they have all become separate from the stele.

The stele closes for some distance above the stamen traces in all species; in *L. coeli-rosa* a short gynophore is externally visible (fig. 9).

Dorsal carpellary traces arise in a whorl of five on the sepal radii. Median laterals are lacking in *L. chalcadonica*, and arise in a single whorl some distance above the dorsals in *L. coeli-rosa* and *L. coronaria*. In the case of *L. flos-jovis* each dorsal trace branches into three (fig. 14A, B) and at the base of the loculi branches from adjacent dorsals fuse in pairs to form a set of five single traces which stand in the positions usually occupied by commissural median laterals (fig. 14C). In *L. alba* ♀ and *L. dioica* ♀, forms with large capsules, a set of minor freely-branching traces arises between the dorsals and the true median laterals. In all cases the median laterals end at the top of the loculi or the base of the styles.

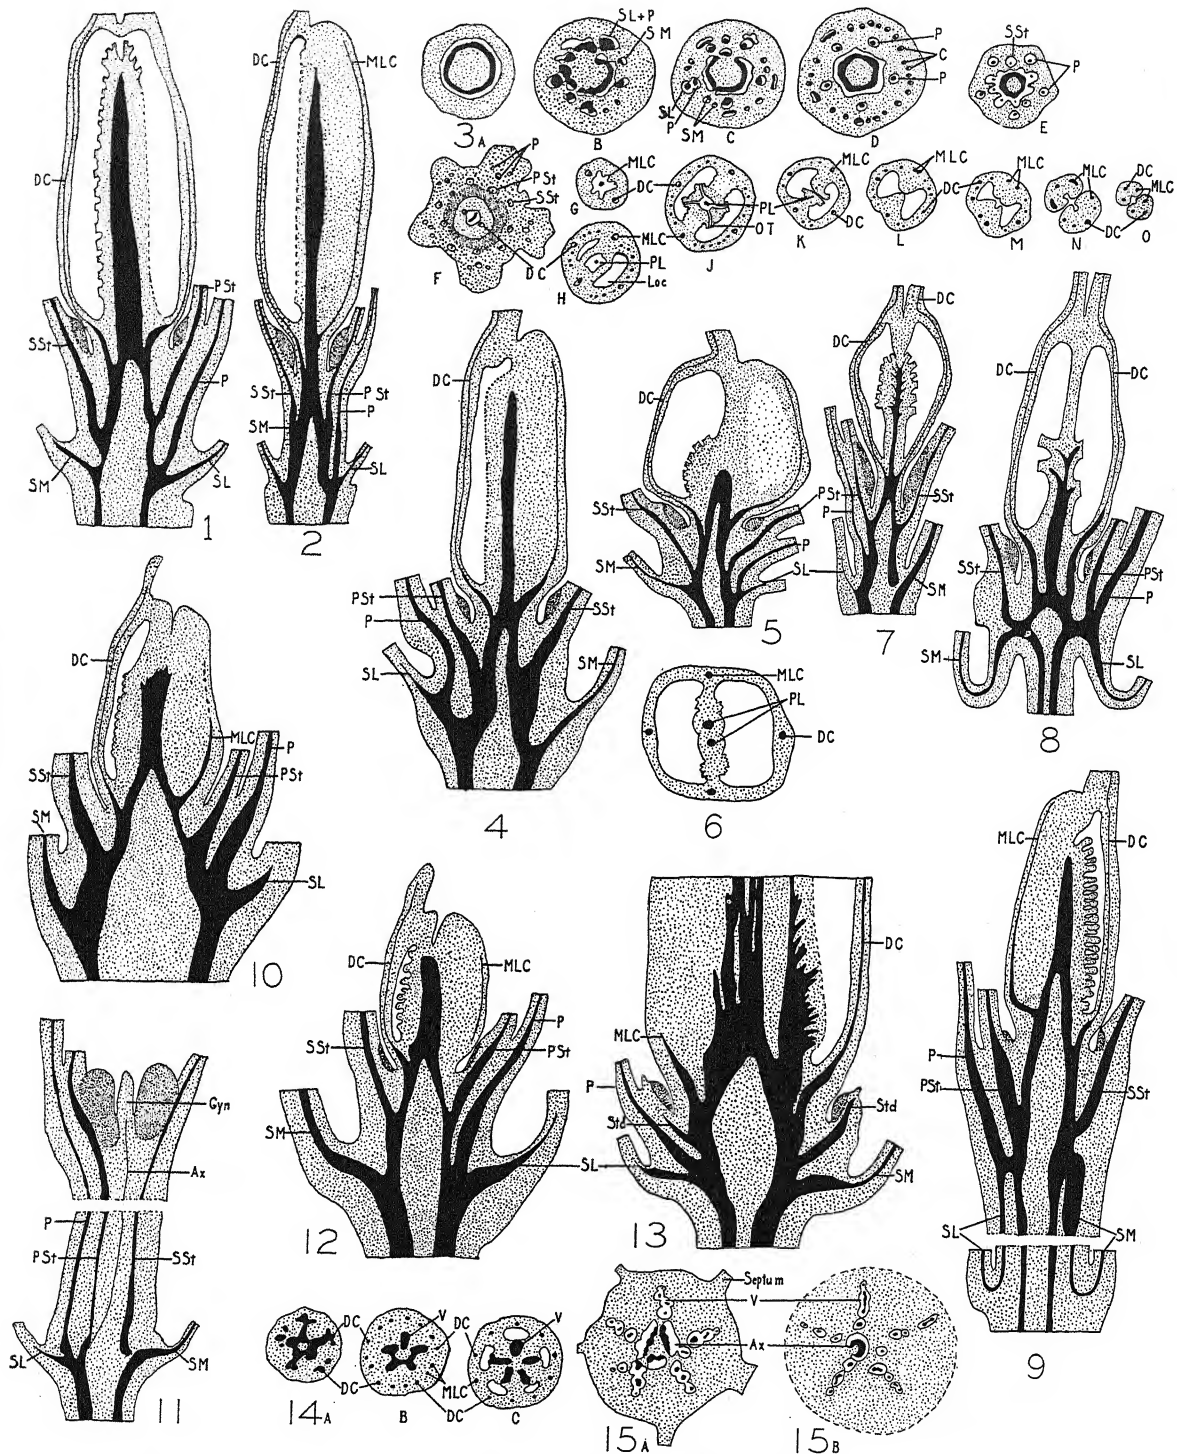

Fig. 1-15.—Fig. 1. *Dianthus chinensis*. Longitudinal section. $\times 7$.—Note: In figures 1, 2, 4, and 5 the gynoecium is represented in such a way as to show both dorsal and median lateral sections; actually the two halves of the gynoecium as shown should stand at right angles to one another. The rest of the flower is represented as it actually appears in section.—Fig. 2. *Dianthus barbatus*. Longitudinal section. $\times 7$.—Fig. 3. *D. barbatus*. Transverse sections from pedicel upward. A, pedicel just below flower. B, whorl of 10 calyx traces depart. C, large strands on petal radii split periclinally into inner petal trace and outer sepal lateral (commissural); sepal midrib trace splits. D, calyx traces divide; stele closes above perianth traces. E, calyx omitted; stamen traces arise, antesealous slightly lower. F, at base of gynophore; calyx omitted; petal traces split into three; antesealous stamen strands stand slightly farther out in recep-

The central vascular remnant consists of a complete cylinder, the pith of which is domed over in the base of the placenta. The vascular core above the pith has the form of a star, from the points of which arise the ovule traces. A strand of xylem elements forms an axis up the center of the placenta. In many sections, especially of *L. alba* ♀ and *L. dioica* ♀, the placenta shows a central vascular core with the arms or rays of the star detached from it and forming a ring around it. In such sections the core may form an almost complete cylinder with no gaps in front of the placental rays (fig. 15A, B). In these two species the xylem in the peripheral strands or rays is arranged as a central strand or a radial plate, as though the carpel edges met and fused, with adaxial faces together, but were not infolded (fig. 36). At the top of the loculi these vascular plates split radially and the adjacent halves fuse in pairs so that each septum as it withdraws from the center has one composite strand. These strands die out with the topmost ovule traces.

In *L. alba* ♂ (fig. 11) and *L. dioica* ♂ the gynoecium is represented by a parenchymatous finger with a central core of elongated, darker staining cells which seem to attach downward to the inner face of the vascular cylinder about at the level where the stamen traces originate.

L. dioica has been described by van Tieghem (1867), Henslow (1890), and Olbers (1895). These accounts agree with the observations presented above. Van Tieghem mentions the presence in the center of the placenta of vascular tissue which represents axis. In another work (1898, fig. 175f, p. 390) he shows a cross section of the placenta of *Lychnis* with five vascular rays as described above, and in the center of the placental column a ring of five vascular bundles with xylem toward the center. Lister (1883) figures a section of *L. dioica* (*L. diurna*) which shows a dark area, presumably vascular, in the center of the ring of arcs which represent the five placental bundles (Pl. 32, fig. 9). Dickson

(1936) shows a vascular patch in the center of the placenta in *Melandrium* (*L.*) *album*. Schumann (1889) declared that in *Melandrium* (*Lychnis*) *album* and *L. coronaria* the antepetalous stamens are inserted higher than the antesealous. Saunders' (1932) description of *L. chalcidonica*, *L. coeli-rosa*, and *L. flos-jovis* agrees with the present observations.

Olbers (1895) described *L. flos-cuculi* as having calyx traces arising in a whorl of ten, petal traces and antesealous stamen traces independent from the stele, antepetalous stamen traces fused at the base with petal traces, median lateral carpellaries lacking. *L. viscaria*, according to the same paper, is similar except that the calyx is saccate at the base and median lateral carpellaries are present and arise in a whorl above the dorsals.

Silene K 5, C 5, A 5 & 5, G 3.—Five species were studied: *S. viridiflora*, *S. pennsylvanica*, *S. noctiflora*, *S. pendula*, and *S. latifolia*.

The pedicel is traversed by a ring of five vascular strands which unite to form a short cylinder at the base of the flower.

The calyx is supplied by a single whorl of ten traces, five on midrib radii, the alternate five on petal radii. In *S. latifolia* the commissural traces branch into two or three strands immediately after leaving the stele. In this species and in *S. pendula* the base of the calyx is saccate or inflated, with the result that the sepal traces recurve sharply at the base (fig. 17).

The petal traces arise from the same ribs on the stele as the commissural calyx traces, but the two whorls are not really fused (fig. 18).

Stamen traces arise in a whorl of ten, antesealous ones independently from the stele, antepetalous ones from the same ribs as petal traces, except in *S. noctiflora*, where petal and antepetalous stamen traces are very slightly fused at the base (fig. 20). The outer tissues of petal and filament remain fused for some distance, often after the petals have separated from one another.

tacle; glandular ring on adaxial face of stamen bases; dorsal carpellary traces arising. G—O, gynoecium only. G, departure of median lateral carpellaries and extra traces for ovary wall. H, base of loculi. J, ovuliferous region showing placental strand with core of xylem, and attachment of ovule traces. K, top of loculi, septa pulling apart and placental trace split. L, M, juncture of ovary and styles; median lateral trace splits, septa bilobed at top. N, O, styles, showing dorsals and median laterals in styles, other traces died out. All $\times 14$.—Fig. 4. *D. armeria*. Longitudinal section. $\times 28$.—Fig. 5. *Gypsophila elegans*. Longitudinal section. $\times 14$.—Fig. 6. *G. elegans*. Section at top of ovary showing placental trace split just before septa pull apart. $\times 28$.—Fig. 7. *G. muralis*. Longitudinal section. $\times 28$.—Fig. 8. *Saponaria calabrica*. One half of distance between calyx and base of glandular ring omitted. $\times 14$.—Fig. 12. *L. flos-jovis*. Longitudinal section. $\times 28$.—Fig. 13. *L. dioica* ♀. Longitudinal section showing traces to staminodes, and nature of placental strands. $\times 14$.—Fig. 14. *L. flos-jovis*. Sections through base of ovary showing origin of median laterals. A, dorsals fork into 3. B, ring of 15 strands destined for ovary wall, two strands between adjacent dorsals. C, at base of loculi wall contains 10 strands, one median lateral where there had been two. $\times 28$.—Fig. 15. *L. alba* ♀. Sections through placenta showing vascular tissue representing residual axis. A, base of loculi. Vascular tissue forms five radiating arms and a central cylinder with gaps. B, in ovuliferous region. Ovule traces supplied from ends of arms; stem residue forms an incomplete cylinder closed in front of most arms. $\times 14$.—SM=sepal midrib. SL=sepal lateral. P=petal trace. SSt=antesealous stamen. PST=antepetalous stamen. Std=staminode. DC=dorsal carpellary trace. MLC=median lateral carpellary trace. V=ventral carpellary strand. Ax=residual axis tissue. PL=placental strand (carpel and stem tissue not distinguished). X=xylem. OT=ovule trace. Loc=loculus. Glandular areas densely shaded. Where a distinction is made in the vascular bundles, dark area=xylem, unshaded=phloem, parenchyma, and procambial tissue.

Fig. 16-36.—Fig. 16. *Silene pendula*. Upper part of capsule showing septa slightly withdrawn from center. $\times 14$.—Fig. 17. *S. pendula*. Longitudinal section. Septa torn. $\times 14$.—Fig. 18. *S. latifolia*. Transverse section of flower between departure of sepal traces and of petal traces showing stellar ribs. $\times 7$.—Fig. 19. *S. latifolia*. Longitudinal section. $\times 7$.—Fig. 20. *S. noctiflora*. Longitudinal section of young flower. Septa complete. $\times 28$.—Fig. 21. *S. latifolia*. Transverse sections of base of ovary. A, dorsal carpellaries separate. B, departure of median lateral and extra lateral traces. C, traces to ovary wall separated, placental supply consists of three arcs with xylem toward center. D, at base of loculi. Ventral supply forms hollow triangle, from points of which arise ovule traces. A-C $\times 12$, D $\times 7$.—Fig. 22. *Cerastium arvense*.

In *S. pendula* the whole base of the flower is much elongated (fig. 17); epidermal cells may be several times as long as they are wide in this region. A stelar internode occurs above the stamen traces; in *S. latifolia* (fig. 19) and *S. pendula* this is elongated into an externally visible gynophore.

The adaxial side of the briefly fused filament bases is glandular, forming a nectar cup around the base of the ovary.

In most species the stelar cylinder closes above the departing stamen traces, but in *S. viridiflora* the stele consists of six strands throughout this internode.

From the angles of the now triangular stele arise three dorsal carpellary bundles, which may branch in the ovary wall. The three strands left after the dorsals depart veer toward the center, flattening to form a hollow triangle which is usually open at the apices. From the abaxial face of each side a single median lateral carpel trace arises. This arrangement is complicated in *S. latifolia* by branching or dissection of strands and by the fact that the median laterals leave gaps (fig. 21). In *S. pendula* and *S. noctiflora* the median laterals bifurcate just before they die out at the top of the ovary. The vascular strands left after the departure of median lateral traces become the placental supply; this assumes the form of a hollow (*S. latifolia*) or solid triangle, from the attenuated points of which arise the ovule traces in pairs (fig. 21D).

S. noctiflora, *S. pennsylvanica*, and *S. viridiflora* show a small central strand of xylem elements in the ovuliferous region of the placenta. In *S. latifolia* and *S. pendula*, where the receptacular pith extends into the base of the placenta, the inner face of the stelar cylinder is occupied by a strip of xylem cells (fig. 21D). In the upper part of the ovary the placental vascular strand trifurcates, and shortly above this the septa separate and withdraw slightly from the center, as in *Dianthus et al.* (fig. 16).

Septa in young flowers (with immature ovules) are intact. The placental vascular tissue ends with the topmost ovule traces except for a small strand of provascular tissue continuing toward the top of each septum in *S. pendula*.

Dawson's (1936) description of *S. noctiflora* agrees with that given above. Henslow (1890) stated that in *S. inflata* (*S. latifolia*) petal and stamen traces are fused at the base; the material sectioned in the present study showed both sets of stamen traces arising directly from the stele. So far as could be determined from the figures given by Pratt (1932), *S. maritima* follows the plan described above for the family. Olbers (1895) described the vascular anatomy of *S. venosa* and *S. nutans*, in which the only difference from the rest of the family is that the antepetalous stamen traces arise lower than the antesepalous.

TRIBE ALSINEAE.—*Cerastium* K 5, C 5, A 5 & 5, G 5.—Two species were studied: *C. vulgatum* and *C. arvense*.

The pedicel shows a ring of five vascular strands, which closes to form a cylinder at the base of the flower.

A whorl of ten vascular traces departs from the stele. Of these, five become sepal midribs which branch variously in the base of the calyx. The alternate five branch anticlinally into three at a short distance from the stele. Of these three, the resulting lateral strands enter adjacent sepals as sepal laterals; the central strand immediately splits tangentially into petal trace and stamen trace (fig. 22). At the level of this last splitting a whorl of five stamen traces departs from the stele on the sepal radii, close above the sepal midrib traces. Sepal midribs become established in the base of the calyx a shade lower than do the laterals. The difference, however, is slight.

The fused soft tissues of filament and petal bases form a short tube, but the vascular strands for all members are separate and distinct from the base of the tube (fig. 23).

There is a short internode above the sepal-petal-stamen node.

At the base of the ovary arises a whorl of ten traces, the five on sepal radii becoming dorsal carpellaries, the alternate five becoming median laterals. The former extend into the styles, the latter end at the top of the loculi. The placental vascular supply forms a solid core with five lobes directed toward the loculi. This vascular core ends with the

ovule traces. In *C. vulgatum* a central strand of one to three xylem elements is surrounded by five small xylem strands in the placental lobes. The whole central area of the placenta is procambial, with indistinct limits. The ovary is completely partitioned, but the septa are fragmentary and loosely woven from an early stage. The placenta is large and round in cross-section, and fragmentary except for the five arms or radially arranged plates to which the ovules

attach (fig. 25). Styles are set back from the center of the ovary—that is, they stand above the loculi rather than above the placenta.

Saunders (1932) states that in *C. arvensis*, *C. chloeraefolium*, and *C. alpinum* the vascular bundles for sepals, petals, and two stamen whorls turn out as one whorl. This would mean that antesepalous stamen traces arise fused with sepal midribs. The material sectioned in the present study shows antesepalous

stamen traces arising independently, although they stand close above the sepal midribs (fig. 22, 24).

Stellaria K 5, C 5, A 5 & 5 to 3, G 3.—Four species were studied: *S. media*, *S. graminea*, *S. holostea*, and *S. aquatica*.

Except for the gynoeceium of *S. aquatica* the species of *Stellaria* examined are essentially similar in vascular pattern to *Cerastium*. Differences found are:

1. The petal-sepal lateral-antepetalous stamen strand is less massive at its origin. The sepal laterals depart from the petal strand farther from the stele than does the antepetalous stamen trace (fig. 29).

2. Antesepalous stamen traces are slightly fused with sepal midribs in *S. graminea* and *S. holostea* (fig. 26).

3. The dorsal carpellary bundles arise slightly lower than the medians in *S. media* and *S. graminea* (fig. 26, 28, 29).

4. The placental or ovuliferous column is somewhat shorter in proportion to the length of the capsule in most cases.

5. Styles stand over the placental column as in most genera.

6. The ovary of *S. aquatica* differs from the others examined. It consists of five carpels rather than three, and the loculi are antepetalous, thus breaking the regular alternation of whorls. Dorsal carpellaries arise in a whorl of five, each of which branches into three near its base. The side branches from adjacent dorsals fuse below the loculi; these fused bundles become median carpellaries (fig. 27A, B).

In this species the general form of the capsule is more like *Cerastium* than like other *Stellaria* species in that it is more elongate and that almost the entire placental column is ovuliferous.

In the highly variable *S. media* no vestigial vascular traces were found at the site of missing stamens. The five-stamen form is like a ten-stamen flower, as of *S. media neglecta*, with the antepetalous stamens completely removed. In forms with less than five stamens the remaining stamens stand in three or four of the normal stamen positions (fig. 28). The only trace of a missing member is a slight bump frequently present on the glandular ring at the site of the deleted stamen.

According to Wester (1899) the calyx midribs of *S. graminea* arise slightly lower than the laterals; otherwise her description of this species and of *S. (Malachium) aquatica* agrees with the writer's observations. Stroebel (1925) declared that *S. holostea* is obdiplostemonous by ontogeny and by insertion. He gave no illustrations nor any more specific information on this point.

Peterson (1936) studied chromosome numbers in the *S. media* group and concluded that *S. neglecta* is the point of departure for the morphologically reduced forms; the latter are considered autotetraploids with a few chromosomes missing from the 2n number in some cases.

Arenaria K 5, C 5, A 5 & 5, G 3.—One species was studied: *A. groenlandica*.

A whorl of ten traces leaves the central cylinder at the base of the flower. At a short radial distance from the stele each of these ten traces splits tangentially. Strands resulting on sepal radii become a sepal midrib and an antesealous stamen trace; of those on the petal radii, the inner becomes an antepetalous stamen trace, the outer subsequently branches into three, of which the middle member becomes a petal trace and the laterals become marginals for adjacent sepals (fig. 31).

The soft tissues of sepal, petal, and filament bases are fused into a short tube or cup about the base of the ovary. The filaments of the antepetalous stamens remain joined to the petals after the petals have separated from one another (fig. 32).

Dorsal carpellary strands arise as a whorl of three. Median lateral bundles are lacking.

The relatively long ovary is completely septate, but the partitions early become fragmentary. The placental column is complete from base to apex of the loculi, but ovules are borne on only the middle third of this column (fig. 31). The placenta is traversed by the usual slender core of xylem cells.

Wester's (1899) description of *A. trinervia* and *A. (Alsine) biflora* agrees with the account given above. Mattfeld (1921) reported that the ovary of *A. (Minuartia) scleranthus* in the young flower is actually sunken in a cavity in the top of the axis. As the capsule grows, it protrudes, but the base remains enclosed by the axis and may be constricted by it.

Spergula K 5, C 5, A 5 & 5, G 5.—One species was studied: *S. arvensis*.

The pedicel bears two or three strands which are separated only by narrow strips of parenchyma and form an almost solid cylinder. Calyx, corolla, and stamens are supplied as in *Arenaria*. Glandular tissue forms a ring on the adaxial face of this tube near its base and extends to the sides of the filament bases.

Of six flowers sectioned transversely, one had only the antesealous stamen whorl developed. In this case no indication of another whorl could be found, either as humps of parenchyma or glandular tissue or as vestigial vascular traces.

After a short stelar internode, a whorl of five dorsal carpellary traces departs on the petal radii. These give rise to various small branches in the ovary wall. Real median laterals are lacking. The placental vascular supply consists of a slender central cylinder with five arms, radiating toward the dorsal carpellaries, from which the ovule traces are supplied. The central pith dies out about halfway up the ovuliferous column. The radial plates or arms of vascular tissue appear in some sections to be detached from the central strand, as in the case of *Lychnis* described above. Toward the top of the placenta all these strands become small and scattered and finally die out.

In young flowers septation of the ovary is complete, although the septa early become loose and fragmentary (fig. 34). The ovuliferous region of the placenta extends about a third of the way up into the capsule.

These observations agree with Wester's (1899) description of the species and with Saunders' (1932) brief mention of it.

Sagina K 4, C 4 (or less), A 4 & 4 (or less), G 4.—One species was studied: *S. procumbens*.

The pedicel is traversed by a complete vascular cylinder.

In the base of the flower a whorl of eight traces leaves the central cylinder. These are distributed to calyx and corolla as in *Arenaria*. In flowers with complete sets of petals and stamens, at the separation of sepal laterals, there is given off a central trace which immediately splits tangentially into petal and antepetalous stamen traces. The number, position, and degree of development of petals and stamens varies widely in this species. Of six flowers sectioned transversely, five had four antesealous stamens and the other had two. Petals and antepetalous stamens may appear as fully formed organs; or as small scales or bumps with very faint and abbreviated vascular traces or no traces at all; or they may be completely lacking with no discernible vestiges. Petals occur somewhat more frequently than antepetalous stamens, but either member may occur at a given corner of the flower.

"Perigyny" is developed to about the same degree as in *Arenaria groenlandica* (fig. 31). In *Sagina* the stamen bases form a short ring or tube above the separation of stamens from petals.

In the short internode below the ovary the stelar cylinder becomes slightly four-lobed. At the base of the ovary a whorl of four dorsal carpellary traces

departs from the central cylinder on petal radii. Above the separation of the dorsals, the placental vascular strand is round in cross-section, becoming X-shaped higher up in the placenta. Ovule traces attach to the arms of the cross. Vascular tissues are weakly lignified and xylem cells difficult to identify in cross section. So far as could be determined, the placenta bears a thin central core of xylem cells.

The placental column extends the entire length of the capsule, but the top third bears no ovules. In the youngest material sectioned (proembryo stage) separation is incomplete in the upper region of the capsule. Ridges occurring on the commissural lines of the ovary wall and on the placenta opposite, between the double rows of ovules, show no sign of tearing or fragmentation. According to Lister (1883) the septa cease vertical growth earlier in development than the ovary wall, so that the capsule is at no time completely septate.

Saunders (1932) shows a cross-section of the gynophore of *S. procumbens* (fig. 51) with eight vascular bundles. The material studied here shows a four-sided cylinder of darkly staining cells with some faintly lignified xylem elements in the center. The dorsal carpellary bundles arise from the angles of this cylinder.

The above observations agree with those of Dawson (1936) on the same species. *S. nivalis* (Wester, 1899) is a pentamerous flower but otherwise shows the same vascular plan.

The entire family is characterized by sepal lateral veins which arise commissurally—that is, as single strands (representing two laterals of adjacent sepals) on the petal radii which show no indication of doubleness until they fork into pairs of marginal veins. These arise in close association with the petal traces. Fusions between whorls do not affect the carpels; in all species examined, a definite stelar internode separates dorsal carpellaries from the traces of lower whorls. Median lateral carpellary traces arise commissurally and show scant sign of doubleness. The two ventral traces for each carpel are completely fused, and in most cases all ventrals are fused into a single vascular core in the placenta. Most of the species examined show a solid column of xylem cells in the center of the placenta; the diameter of this varies with the size of the capsule, but the xylem may be present even in the smallest flowers. In the upper part of the ovary septa do not meet in the center, as though the carpel margins do not quite meet for a part of their length.

The two tribes may be briefly characterized as follows:

Sileneae.—Gamosepaly ranging from simple adherence of soft tissue to fusion or anastomosing of vascular systems; a tendency for all traces supplying perianth parts to form a single whorl, and for all stamen traces to form a single whorl without a reduction in number; stamen traces independent of traces of other whorls; frequent occurrence of a gynophore; indications of incomplete carpel fusion.

Alsineae.—Sepals separate; “perigyny” by fusion of sepal lateral-petal-stamen strands and tissues, and fusion between sepal midrib traces and antesepalous stamen traces in smaller forms with the result that only two whorls of traces depart from the stele to supply all floral members; variability and reduction in number of petals and stamens; sometimes a change in alternation sequence with reference to carpels; progressive reduction in size of whole flower, of ovuliferous region of placenta, and of venation in carpel wall.

Details are summarized in table 1.

DISCUSSION.—The anatomy of the species here investigated shows a progressive telescoping of whorls along the floral axis, affecting first the lowest whorls. The sepal is a three-trace organ as in the leaves of most Centrospermae (Sinnott, 1914). The laterals of sepals arise commissurally throughout the family, as in many angiosperms in widely scattered families. In a few cases among the *Sileneae* the sepal midribs arise lower than the commissurals, as in *Dianthus armeria* and some species of *Lychnis*, but in most species the two sets of traces arise at the same level. The next stage of condensation is adherence between sepal commissurals and the superposed petal trace. In *Lychnis* and *Silene* these two whorls are separated by a short vertical distance, but arise from the same ridges or ribs on the stele (fig. 18). In other genera there is actual fusion of the basal parts of the superposed traces.

The internode that is externally apparent between calyx and corolla is due to adherence of a saccate calyx base to the pedicel which it surrounds. Anatomically there is no internode here.

Traces for antesepalous stamens arise lower than those for antepetalous in *Dianthus* and *Saponaria*, less so in scattered species of *Silene* and *Lychnis*. In other forms the two sets are contracted into a single whorl. In *Saponaria* and the *Alsineae*, the antepetalous stamen traces arise fused with the petal traces; in some species of *Stellaria*, in *Arenaria*, *Spergula*, and *Sagina* those for antesepalous stamens are fused with sepal midribs. Anatomically none of the species examined is obdiplostemonous. Fusions between perianth and stamen traces are cumulative, that is, if antesepalous stamen strands are fused with sepal midribs, then antepetalous are always fused with petal strands and with calyx commissurals.

Fusion between whorls does not affect the carpels. The ovary is elevated upon a rather short gynophore in *Dianthus*, *Gypsophila*, and a few other *Sileneae*, but a real stalk is never developed in the *Alsineae*. In all species there is a vascular internode between the departure of stamen traces and that of carpel strands. Within the carpel whorl some telescoping is apparent in that the dorsals consistently arise at a lower level than the laterals in the *Sileneae*, but all form a single whorl in many members of the other tribe.

Median lateral traces branch from the dorsals and fuse in pairs, as described above, in the ovaries of *Lychnis flos-jovis* and *Stellaria aquatica*. In other

species these medians arise commissurally, but separation of the component strands occurs at the top of the loculi in many Sileneae. In *Dianthus barbatus* and *D. chinensis* the medians enter the styles, but in other species the forks soon die out. In some Sileneae and all Alsineae the strands die out without forking.

The vascular supply to the ovary wall varies with the size of the capsule. Large capsules bear an extra set of strands between dorsals and median laterals as in *Dianthus barbatus*, *D. plumarius*, and *D. chinensis*, and *Lychnis alba* and *L. dioica*. Small capsules as in *L. chalcedonica*, *Arenaria*, *Spergula*, and *Sagina* develop no medians at all.

In flowers with an isomerous gynoeceium the carpels may be antesepalous, as in *Lychnis* and *Cerastium*, or antepetalous as in *Agrostemma*, *Stellaria*, *Spergula*, and *Sagina*. Since all of these genera bear five whorls of floral parts, of which the outer four arise in acropetal sequence (Payer, 1857) and stand on alternating radii, this variation in location of the carpels has puzzled many morphologists. Explanations based on dedoubement or omission of perianth or stamen whorls are not substantiated by ontogeny nor by anatomy of mature flowers; moreover, such theories may explain one position of carpels or the other, but not both at the same time. Alexander Braun suggested that two whorls of carpels are potentially present, but one is always missing (Eichler, 1875, p. 111).

Hofmeister (Čelakovský, 1875) postulated that primordia arise where there is a gap or an unoccupied space. Čelakovský (1875) studied the problem of obdiplostemony and suggested that in flowers such as those of the Caryophyllaceae with antepetalous carpels the antepetalous stamens have become phylogenetically displaced downward on the axis, so that at the time of carpel initiation the gaps on the axis are antepetalous. Schumann (1899) decided that in *Malachium* (*Stellaria*) *aquaticum* the antepetalous stamens are probably higher than the antesepalous, and that contact at the time of formation is the decisive factor in carpel position.

Saunders (1935) suggested that in flowers where the midribs for all whorls arise directly from the stele, after formation of the second stamen whorl a "state of congestion" is induced. By the time of recovery from this state the spirally advancing "growth impulse" has passed to the petal radii, and carpels arise there. *Agrostemma* has been described by Olbers (1895) as having stamen traces arising in two whorls independently from the stele. So far as I can determine from the literature, a gynophore is no more highly developed here than in *Lychnis*. Other species showing a gynophore have oligomerous gynoecea and are thus not comparable. In both *Stellaria aquatica* and *Cerastium* the antepetalous stamen traces are fused with petal traces, antesepalous arise directly from the stele; the length of the stelar internode above the stamen trace whorls is about the same in both cases. The cause of the discrepancy in position of carpels in these forms is thus not revealed by anything in their mature anatomy. Perhaps a

comparative histogenetic and anatomical study would reveal some pertinent factors.

Stellaria, *Spergula*, and *Sagina* often bear only one stamen whorl. In such cases the alternation sequence of whorls is regular and there is no problem of symmetry. Perhaps spatial relations have some influence on the dropping out of whorls in this family. On this basis it is easy to see why the antepetalous stamen whorl disappears before the antesepalous in these genera; but the cause of the original shift in carpel position remains unexplained.

Nature of the floral parts.—The facts here presented throw no new light on the nature of sepal or stamen. The sepal appears to be a three-trace leaf-like structure, the stamen a one-trace autonomous member. The ephemeral existence of the stamen may be the cause of its weak vascularization. The vascular strand in the filament usually consists of only a few xylem elements in the center of a slender cylinder of parenchyma, phloem, and procambial tissue. The organization of this strand may be truly radial, or it may be that cells on the adaxial side of the bundle never differentiate into mature xylem elements because of the brief life of the stamen. In the light especially of paleobotanical knowledge, Wilson's (1937) concept of the stamen as a reduced branch system comparable in its origin to the angiospermous foliage leaf seems the most tenable idea yet proposed.

The petal has been interpreted as a leaf, as fused stipules of a stamen, and as a metamorphosed stamen. Nothing observed in this study suggests a direct origin from a leaf or a sepal. The texture and venation are distinctly unlike those of leaf and sepal. Anatomically the petal does not resemble a pair of stipules. If the petal is composed of stipules and is homologous with a nectar gland, then stipules of antesepalous stamens are never vascularized while those of alternisepalous stamens always are; the traces for stipules are always fused below the midrib, and so completely fused that the vascular system first branches on a plan of three instead of two; and in the Sileneae the antesepalous stamens have no stipules and are inserted in some species at a level between the alternisepalous stamens and their stipules. The facts can be explained much more simply and with less stretching of facts to fit the argument if petals are considered independent and autonomous organs.

Several substantial facts support the concept of petals as metamorphosed stamens. Extra petals formed in double flowers show a close series of transition forms from stamen to petal (Smith, 1927). Troll (1927) has reconciled the form of petals to their origin from stamens. In double flowers such as cultivated forms of *Dianthus* or *Gypsophila* the vascular strand for an extra member may arise by splitting of a normally placed strand or depart directly from the stele; both situations may occur in the same flower (fig. 35A-D). The extra member supplied by a splitting stamen trace may develop as a stamen or as a petal. The vascular supply for petals consist-

ently arises as a single strand, as in the case of stamens. The tendency to dichotomy in petal venation may indicate a secondary elaboration in response to the needs of an expanded organ.

In general form the carpel resembles a leaflike organ rolled longitudinally, so that the edges meet at top and bottom but are separated for a short distance near the top in the region where the septa withdraw from the center. The bilobed form of the free ends of the septa in this region in *Dianthus armeria*, *D. barbatus*, and *Saponaria calabrica* further suggests the slight separation of two folded laminar organs. Despite the description generally given in taxonomic works of the pistil as unilocular, the capsule is distinctly septate, at least when young.

Anatomically the carpel is a five- or three-trace member in which median laterals of adjacent carpels have coalesced more or less completely. Throughout the family the ventral carpel traces are fused in pairs, forming strands standing opposite the dorsal trace. Often the entire ventral supply forms a central mass in the placenta. In most species the tissues can be roughly allotted to specific carpels because of the arrangement of the placental vascular tissue in rays or arms, each standing opposite a dorsal carpellary bundle and each supplying a double row of ovules; but in the lower portion of the ovary there is often no real demarcation of the separate bundles of which this placental mass is presumably composed. Higher up, where the septa pull apart from the center, the ventral traces separate (fig. 36), one standing in the edge of each septum and each probably composed of the strands of adjacent carpels which have coalesced.

The presence of some residual stem tissue in the ovuliferous region of the placental column is indicated by the central vascular cores described above in *Lychnis* (fig. 15A, B) and *Spergula*. This feature has been figured by several writers but ignored beyond the indication of it in their drawings, except for van Tieghem, who considered it as stem tissue, but of no great significance. The persistence of a xylem strand in the center of the placental column (fig. 25) in even the most reduced forms such as *Arenaria* and *Sagina* suggests that a slight remnant of stem tissue is present. The central pith may be continuous from receptacle to above the departure of median lateral carpel traces, as in all *Lychnis* species examined, some *Silene*, some *Gypsophila*, *Spergula*, *Cerastium*, and some *Stellaria*. Schaefer (1890) suggested that the pulling apart of septa in the upper part of the ovary indicates the level at which the stem ends. Lister proposed that the rudimentary structure in the position of pistil in staminate flowers of *Lychnis alba* and *L. dioica* might be the stem apex which forms no carpels.

All the evidence taken together points to the presence of some residual axis tissue in the center of the placental column. This has been definitely established for some ranalean species (Eames, 1931), and there seems to be no reason for discrediting this interpretation in this family. It does not affect the true

appendicular nature of the placentae, since the stem residue is in excess of the tissues composing the carpels. The presence of such a residue is another aspect of the reduction from large primitive forms.

Since the telescoping described affects the lower or first-formed whorls first, the limitation of growth or reduction in length of the axis must be determined at the very start of floral development.

Newman (1936) considered the carpel of *Acacia* to be a lateral organ; although the amount of tissue representing axis is very small, it can be followed through at least the early stages of carpel formation. McCoy (1940) in a study of the floral histogenesis of *Frasera carolinensis* found that sepals, petals, stamens, and carpels all arise in a similar manner from two distinct superficial and a third inner "germ layers." Brooks (1940) reported that the floral apex in *Amygdalus communis* differs from the vegetative in possessing only one tunica layer rather than four, and that the carpel differs from the other floral parts in that the entire floral apex is involved in its formation. Satina, Blakeslee, and Avery (1940) grew periclinal polyploid chimaeras of *Datura* in which germ layers can easily be distinguished by the characteristic cell size of each layer. Histogenetic studies on such flowers should reveal interesting data, especially on the later developmental stages which are difficult to follow in flowers of homogeneous composition.

Relationships as indicated by floral anatomy.—Within the family the species investigated fall into groups that agree with the general taxonomic treatment. The two tribes Sileneae and Alsineae differ in anatomy as in external characters. Among the former, *Lychnis* and *Silene*, sometimes designated as Lychnidae, are closely similar in the venation of the calyx, where commissurals are fused to a point just below the sinuses, and branches from midribs and from commissurals often anastomose distally; petal traces arise in close conjunction with calyx commissurals, but are in most cases not really fused. *Dianthus*, *Gypsophila*, and *Saponaria* form another closely similar group, sometimes referred to as the Diantheae. In this group, branches from calyx commissurals do not anastomose with midrib branches; petal traces are actually coalesced with calyx commissurals at the base; a gynophore is present in most species; median lateral carpellaries fork at the top; carpels are reduced to two. The two groups probably diverged from a common ancestral form, *Lychnidae* advancing further into gamosepaly and syncarpy, Diantheae showing further adhesion in the perianth, oligomery in the gynoeceum, and reduction of axial residue in the pistil.

The Alsineae can be regarded as a single line, uniform in the vascular pattern of calyx and corolla, with progressive adhesion of stamen whorls to perianth leading to slight but definite "perigyny," and showing progressive reduction in the gynoeceum.

Reduced forms are regarded as derived on the grounds that oligomery, anatomical fusion, "peri-

gyny," and reduction of residual axis tissue are all characters which show increasingly wide departure from the primeval form of flower. This view is further supported by the work of Kraft (1917), who reported that in the course of their ontogeny many species exhibit actual reduction in the number of members by abortion or resorption of primordia; and by that of Matzke (1932) showing that oligomerous flowers in *Stellaria media* most often exhibit radial or bilateral symmetry, but that this symmetry is limited by the disposition of parts in the most complete ground plan.

Further reduction from forms such as the more reduced Alsineae leads to the Paronychieae, which merge into reduced Centrosperms families such as the Chenopods and Amaranths.

The anatomical facts here presented support the view of Douglas (1936) and Dickson (1936) that the Primulaceae may be derived by further reduction of the septa from Caryophyllaceae. In both families traces for calyx and corolla are closely related; stamens show a tendency to epipetaly by adhesion of soft tissues in the Sileneae, and in the Primulaceae the vascular strands for these two whorls also coalesce; the vascular plan in the gynoecium is similar in the two families, although the ventral strands of Caryophyllaceae often show coalescence into a placental mass. Dickson (l. c.) concluded that residual axis tissue is present in the placenta, but no specific vascular tissue could be allotted to the axis; the Primulaceae thus show a variation from the Caryophyllaceae in further reduction of residual stem tissue.

The derivation of the Caryophyllaceae from the Geraniaceae as suggested by Dickson is less convincing. The latter family is characteristically obdiplostemonous with antepetalous carpels. The arrangement of stamens can be explained by the occurrence in some forms of vestigial traces of a third and outermost stamen whorl standing just above the sepals. Traces for stamen and perianth whorls show fusions similar to those occurring in Caryophyllaceae and Primulaceae, but there is no indication of a third stamen whorl in either of these two families. The Caryophyllaceae were shown above to be truly diplostemonous. The number of floral whorls as fixed in primitive ancestral forms would seem to be a more fundamental test of relationships than the occurrence of similar types of vascular fusions arising

presumably as a result of shortening of the floral axis, which happens in all floral lines.

The Polemoniaceae (Dawson, 1936) show a fundamental vascular plan comparable to that of Primulaceae and Caryophyllaceae. Noteworthy is the occurrence of a central xylem strand in the placenta of many polemoniaceous species, as well as in many of those here investigated. This has not been reported for other groups. The most striking deviation of the Polemoniaceae from the other families is the lack in this group of a tendency to suppress carpelary septa. The three families may be regarded on the basis of their floral anatomy as parallel lines, possibly stemming from a common ancestor, with the Polemoniaceae diverging before the weakening of septa and attaining a comparable degree of reduction and fusion.

SUMMARY

The vascular anatomy of the flower is described for twenty-nine species in ten genera of the Caryophyllaceae.

The anatomy of the species investigated shows progressive telescoping with consequent coalescence of whorls and their vascular traces along the floral axis, affecting first the lowest or outermost whorls.

Explanations of the inconstant location of the carpels are discussed.

Anatomical data support the concept of the petal as a metamorphosed stamen, of the carpel as a folded leaflike structure. The capsule in flowers up to the stage of anthesis is completely septate except in the case of *Sagina*. Vascular tissue representing residual axis tissue is present in the placenta, especially in the Lychnidae. Ventral carpel traces are coalesced into a central placental mass or into a group of separate strands.

The anatomy of the species investigated supports the usual taxonomic treatment of relationships within smaller groups in the family. The Alsineae are a more reduced and anatomically more advanced group than either section of the Sileneae.

The relationship of the Caryophyllaceae to the Primulaceae is upheld, but direct relationship to the Geraniaceae seems improbable, and to the Polemoniaceae remote.

Note that thin black lines hold up fairly well in reduction, but that small black dots and small white spaces between black lines or dots may be lost. If placed too close together, dots and lines produce black blotches when the drawing is reduced. Keep the shading rather open. The degree of reduction needs to be known before the drawing is inked in.

Delicate shading may be obtained if the size and spacing of the dots are adjusted to the degree to which the drawing is to be reduced.

POPULATIONS OF LINARIA ON THE GULF COAST ¹

Norman C. Fassett

ABOUT PENSACOLA, Florida, occur all three of our native North American species of *Linaria* (Pennell, 1935, maps 82-84). These are: *L. texana* Scheele, which is widespread west of the Mississippi River but eastward is confined to the southern states; *L. canadensis* (L.) Dumort, common eastward, especially on the Atlantic Coastal Plain, and of scattered occurrence west of the Mississippi River; and *L. floridana* Chapman, of peninsular Florida and the Gulf Coast, with one record from the interior of Georgia.

In April, 1941, the writer made mass collections of *Linaria* about Pensacola and at points inland as far as Atlanta, Georgia. The procedure consisted simply of taking many individuals from each patch of *Linaria*; a number of whole plants were taken and these were supplemented with inflorescences from many additional plants. If a patch had less than fifty individuals, each individual was ordinarily sampled; in very large colonies about fifty individuals were taken at random.

It was found that any patch may consist of one species, or of two species, or of all three species intermixed. Table 1 shows the number of individuals of each species collected in each patch. The stations are arranged in order of distance from the Gulf of Mexico.²

ECOLOGY.—Soil requirements of the three species appear to be identical. About Pensacola, any patch of recently disturbed sand may have any or all species. Anderson (1933) observes that *Iris versicolor* and *I. virginica*, which appear to have entered the

southern peninsula of Michigan at different times, very rarely grow together. There is apparently no such exclusion of one species by another in the colonies of *Linaria*.

Two species sometimes occupy the same habitat, but one is more limited than the other. Such a pair is *Phyllitis Scolopendrium* and *Polystichum Lonchitis* as they occur in Bruce Peninsula, Ontario. Where the *Phyllitis* is found the *Polystichum* is commonly found also, but the converse is not true, for the *Polystichum* is frequently found not accompanied by the *Phyllitis*. It would seem that the occurrence of the *Polystichum* is limited by a certain set of factors, and that of the *Phyllitis* by the same set of factors plus others. The ranges of these two ferns are consistent with this hypothesis, for *Polystichum Lonchitis*, while somewhat local, is widespread in North America (Fernald, 1935, p. 207), but the American phase of *Phyllitis Scolopendrium* is known from but four small areas (Fernald, 1935, p. 200). This case is cited only to serve as a contrast with the *Linaria* situation. *L. floridana* is found, in this part of its restricted range, only along the Gulf of Mexico, and is quite absent from all collections not taken close to the coast. Yet where it does occur it outnumbers the two more widespread and presumably more aggressive species. Why does it fail to spread inland (except for the single inland collection recorded by Pennell, l.c.)? There must be some factor, favorable to *L. floridana* and operative only along the coast (possibly climatic?), to which the other two species are indifferent.

TAXONOMY.—These are three distinct species. All the specimens examined for table 1 had flowers or mature fruits, and most of them had both. There was no question of the specific identity of any individual. And yet *L. canadensis* shows many identical characters, on the one hand with *L. texana*, and on the other with *L. floridana*; in its only unique characters

TABLE 2. Characteristics of the three species of *Linaria*.

	<i>L.</i> <i>texana</i>	<i>L.</i> <i>canadensis</i>	<i>L.</i> <i>floridana</i>
Seeds tuberculate, with rounded edges	×
Pedicels glabrous	×
Corolla 10 mm. or more long.....	×
Spur 5-7 mm. long.....	×
Pedice! shorter than the corolla.....	×	×	..
Spur slender	×	×	..
Corolla 7-10 mm. long.....	..	×	..
Spur 2-6 mm. long	×	..
Seeds nearly smooth, with sharp edges.....	..	×	×
Pedicels glandular ^a	×	×
Spur 0.5 mm. long.....	×
Corolla 5-6 mm. long.....	×
Pedice! longer than the corolla.....	×
Spur stout	×

^a *L. canadensis* is commonly described as having glabrous pedicels, but they are glandular on nearly every herbarium sheet examined. In the material of table 1, only the plants of Collection 7 lacked stalked glands, and on these plants the pedicels were so glutinous that grains of sand were adhering to them.

it is intermediate between these two. Table 2 shows the characters of the three species.

On the basis of similarity of flowers, which differ only in size, *L. texana* was at one time reduced (Pennell, 1922, p. 502) to a variety of *L. canadensis* (later to be reinstated as a species by the same author, 1935, p. 302). But, with as sound logic, *L. floridana* and *L. canadensis* might, on the basis of similarity of seeds, be considered as conspecific. Should all three, then, be considered as phases of one polymorphic species? They definitely should not, for in spite of their rather inconspicuous differences and their habit of growing together they remain always perfectly distinct. The 43 individuals in Collection 1, for example, constitute not one variable population, but three distinct populations, which happen to be growing in the same place but among which there is apparently no gene flow.

The only suggestion of hybridization in the group is in Dr. Pennell's report (1935, p. 302) of seeds intermediate in character between *L. canadensis* and *L. texana*, in a belt from Missouri to Texas. Of the nearly 300 individuals examined in table 1, the only one which has any apparent possibility of interchange of characters is in Collection 3 from sandy soil about a recently built house (temporarily serving as the Gulf Breeze Post Office) near the south end of the Pensacola Bridge. This individual, only 12.5 cm. tall, has very small capsules about 1.5 mm. long, and copiously glandular pedicels which are but 3-5 mm. long, much shorter than in normal *L. floridana*. The seeds, while not like those of *L. texana*, have obtuse angles but show to some extent the pebbled surface characteristic of *L. floridana*. There were several hundred individuals in this patch, of which 58 were collected, and all proved to be *L. floridana*.

CONCLUSION.—*Linaria floridana*, *L. canadensis* and *L. texana*, as they occur on the Gulf Coast, meet the definition of species as given by Darlington (1940, p. 150): "the minimum permanently isolated

groups." External isolating factors, such as distribution, habitat preference and flowering time, do not appear to be operative, but internal barriers are sufficient to keep them as three distinct populations.

SUMMARY

Mass collections, consisting of many individual plants or inflorescences from each colony, have been made of the three native species of *Linaria*—*L. floridana*, *L. canadensis* and *L. texana*—from Pensacola, Florida, to north-central Georgia. About Pensacola, where the ranges of the three overlap, they occur together and all flower at the same time. In spite of this fact and the fact that *L. canadensis* is intermediate between the other two, the three species are always perfectly distinct. It is concluded that they represent three populations (therefore, three valid species), which are isolated by internal barriers in lieu of isolation by such external barriers as geographic range, ecology or different flowering seasons.

PRESENCE OF ANTI-HEMORRHAGIC MATERIAL IN ROOTS OF EUROPEAN BINDWEED (*CONVOLVULUS ARVENSIS* L.)¹

Arthur L. Bakke and Norman D. Render

IN PREPARING roots of the European bindweed (*Convolvulus arvensis* L.) for chemical and physiological studies of root reserves, the root tissue was cut into small sections to facilitate drying. For this purpose, a sharp butcher knife was used, and several times during this process the point of the index finger was accidentally cut. Although the cuts were sufficient for profuse bleeding, bleeding stopped immediately. It was noticed also that the cuts healed readily without any treatment. The experiments submitted in this paper represent an attempt to determine whether a blood-clotting property is present in the roots of the European bindweed.

European bindweed roots were dug, immediately washed and the moisture adhering to the surface removed with the aid of dry cheese cloth. The roots were cut into small pieces, steamed for ten minutes and then placed in a dehydrator (Hixon and Bakke, 1939), where the material was dried under forced air at a temperature which was never above 70°C. When the material was thoroughly dry, it was stored in the dark. Five grams of the powdered root material were placed in a mortar to which 100 cc. of distilled water were added. After mixing thoroughly for ten minutes, the extract was separated from the solid material by filtering through a Büchner funnel. In all cases, the extract was prepared a short time before using. The saline extract was prepared in the same manner except that a physiological salt solution (0.9 per cent) was used instead of distilled water. The solutions were of a chocolate brown color.

In making the blood tests, the patient placed his hand upon the table with palm down. By means of a sharp scalpel provided with a guard so as to penetrate the flesh to a uniform depth, an incision was made in the first joint of the finger. When fewer than four solutions were used, the thumb was not included. Absorbent cotton pads 5×5 cms. were soaked with the extracts and as soon as the incisions were made, were placed directly over the bleeding part. A pledget soaked in distilled water served as a control. Distilled water may possibly have a laking effect on blood. As distilled water and physiological salt solution were considered separately as far as solvents for the bindweed material, the selection of water as a control was entirely logical and valid. At the end of each second, determined by means of a stop watch, the pad was removed and a strip of white blotting paper was immediately placed in contact with the

bleeding part of the finger causing a spot to be formed on the paper. A pad with the extract was again placed on the bleeding part and at the end of one second was again removed to permit the blotting operation. When no spots appeared on the paper on three successive contacts, bleeding was considered to have stopped. When all bleeding had ceased, the spots on each strip of blotting paper were counted. The number of spots on the blotting paper then represented the number of seconds necessary for the completion of bleeding or for the clotting of the blood. If the moistened pledgets became soiled to excess, new pads were used. The data were obtained voluntarily from patients in the psychopathic ward of the Cherokee State Hospital and are presented in the tables.

In tests involving seventeen different individuals (table 1), the saline and water extracts accelerated the blood clotting in all trials, with the exception of patients 4, 13 and 15. The solution used on No. 4

TABLE 1. Blood clotting time as affected by saline and water extracts of European bindweed roots measured by the number of blood spots obtained at one-second intervals upon white blotting paper when placed in contact with the bleeding part (Duke's method).

* Solutions one half as strong as those used on other patients.

however accidentally became one half as concentrated as the other extracts. The averages were as follows: physiological salt solution 18, water extract 16, control 28 seconds. In a statistical analysis² of the data, the variation in the response from the different treatments was found to be highly significant.

16	18	16	10	17	17

If this blood-clotting material is present in the roots of the European bindweed, it seemed logical to expect that it might be present in the leaves and stems of this plant, that is in the chlorophyll-bearing tissue. Aqueous extracts were made of the dried leaves and stems of the bindweed. The same control as formerly used was employed, but in addition an aqueous extract of the chlorophyll-bearing parts of the alfalfa plant was introduced as it was readily available and at the same time credited with containing the anti-hemorrhagic vitamin K (Dam, 1929, 1930). The aqueous extract of the alfalfa was of a yellowish green color. On the other hand the aqueous extract of the leaves and stems of the European bindweed was of a dark brown color somewhat darker than the root extract. The results of the eight series of determinations involving the three different plant tissues along with the control are presented in table 2.

The data in table 2 show that the extracts of the bindweed roots and the chlorophyll-bearing parts have a retarding effect on bleeding time in humans. The saline extract of the root tissue of the European bindweed generally gave lower blood-clotting values than was present for the water extract of the leaf and stem tissue of the same plant. Of course it is realized that the evidence was drawn from only eight cases. In a statistical analysis of these data, the degree of variance in the response from the different extracts was significant.

In examining the data further, it is clear that there is present some constituent (or constituents) in the roots of the European bindweed which accelerates

the clotting of human blood. The material is water soluble or soluble in a weak salt solution. Being water soluble, it cannot be placed directly in the vitamin K category (Smith *et al.*, 1939). Whether the European bindweed material will act in the same way as young chlorophyll-bearing parts of alfalfa or grasses or phythiocol must await experimental evidence. As the European bindweed is plentiful and readily obtained, it may find a place in the production of valuable therapeutic compounds.

SUMMARY

The results of this study show that there is present in the European bindweed (*Convolvulus arvensis* L.) a substance (or substances) which causes the clotting of human blood.

A CYTOLOGICAL STUDY OF SOME SPECIES IN THE TRIBE PANICEAE¹

Glenn W. Burton

Most of the grasses now included in improved pastures in the Southeast belong to the tribe Paniceae. Many of the native grasses in this region are likewise members of this large tribe, which is confined primarily to the tropical or semi-tropical portion of the world.

Comparatively few species in the Paniceae have been studied cytologically. The chromosome counts that have been reported for members of this tribe have been assembled in table 1. The need of more cytological information on these grasses, some of which are included in the grass breeding activities at the Georgia Coastal Plain Experiment Station, Tifton, Georgia, motivated the cytological investigations reported here.

MATERIALS AND METHODS.—Most of the *Panicum* species and several of the other grasses mentioned in this study were obtained from Mr. George E. Ritchey at the Florida Agricultural Experiment Station, Gainesville, Florida. They were collected as promising specimens in some of the native pastures in Florida and were planted for observation in Ritchey's introduction garden. They were identified with the aid of the Manual of Grasses of the United States (Hitchcock, 1935) and identifications were checked by Mr. J. R. Swallen, U. S. Department of Agriculture, Washington, D. C. Vegetative material of these plants was grown in the greenhouse at Tifton, Georgia, for root tip production.

Root tips from all of the grasses studied in this report were collected between 8 and 10 A.M. and were fixed in Craf fixative for twenty-four hours. The embedding procedure consisted of a slight modification of the alcohol-chloroform method as revised by LaCour (1937). Sections were cut 10 μ thick and were stained by the iodine-gentian violet technique described by LaCour. All chromosome numbers were determined by making camera lucida drawings of several different equatorial plates in each species. The drawings were made at table level using a 1.5 mm. objective and a 25 \times ocular, and all have the same degree of magnification.

OBSERVATIONS.—A list of the Paniceae examined, together with their somatic chromosome numbers and their source, is presented in table 2. Herbarium specimens have been made of most of these grasses, and these have been deposited either in the herbarium of the University of Florida at Gainesville or in that of the Coastal Plain Experiment Station,

Tifton, Georgia. A brief discussion of each species follows.

Panicum antidotale Retz. F. C. 22396.—This rather tall, stemmy species, obtained from Mr. S. A. Hagler, Fulton, Kentucky, has been quite susceptible to disease at Tifton, Georgia, and has grown well only on soils of unusually high fertility. Since the data presented in tables 1 and 2 indicate that 9 is the most common basic chromosome number in this genus, the plants examined here may be considered diploid, 2n=18 (fig. 1).

¹ Received for publication January 2, 1942.

Cooperative investigations at Tifton, Ga., of the Division of Forage Crops and Diseases, Bureau of Plant Industry, U. S. Department of Agriculture, the Georgia Coastal Plain Experiment Station, and the Georgia Experiment Station, Experiment, Ga. The writer is indebted to E. J. O'Neal, Agent, U. S. D. A., Tifton, Ga., for assistance in the preparation of material for cytological study and to George E. Ritchey and Miss Lillian E. Arnold, Associate Agronomist and Assistant Botanist at the Florida Experiment Station, Gainesville, Fla., for some of the grasses examined in this study.

Panicum arenicoloides Ashe.—This perennial bunch grass, which is adapted to the sandy pine woods of the Southeast, has 18 somatic chromosomes (fig. 2).

Panicum commutatum Schult.—Although found in most of the states east of the Mississippi River, this perennial grass is of limited economic importance. The specimen examined showed the 2n number to be 18 (fig. 3).

Panicum anceps Michx.—This rather large, rhizomatous perennial has been found growing in moist sandy soils from New Jersey to Kansas and south to the Gulf of Mexico. Since Nielsen (1939) reported 18 somatic chromosomes in a plant of this species collected in Rosston, Arkansas, the count of 36 here obtained for the Florida specimen demonstrates the existence of intraspecific chromosome races in this species (fig. 4).

Panicum sp. L. P. I. 126491.—Mr. Swallen reports that this introduction from Australia does not fit descriptions in the manuals and, hence, is still unidentified. The material examined was tetraploid, 2n=36 (fig. 5).

Panicum purpurascens Raddi.—Paragrass, a stoloniferous, robust perennial, is palatable, nutritious, and highly productive. In tropical America it is one of the best pasture grasses, supporting several mature cattle per acre under favorable conditions. Its cold susceptibility restricts it largely to the State of Florida. It was found to have 36 somatic chromosomes (fig. 6).

Panicum fasciculatum Swartz.—This vigorous annual, commonly called brown top millet, is cultivated in the Southeast for its seed and forage. Root tip cells contained 36 chromosomes (fig. 7).

Fig. 1-27. Camera lucida drawings of chromosomes on equatorial plates in cells from root tips of the following Paniceae.—Fig. 1. *Panicum antidotale* F. I. 77998, 2n=36.—Fig. 24. *D. polezansii* P. I. 111105, 2n=34.—Fig. 25. *D. decumbens* P. I. 111109, 2n=30.—Fig. 26. *D. sp.* P. I. 111128, 2n=36.—Fig. 27. *Axonopus affinis*, 2n=80. Magnification of all figures ca. 2,000X.

Panicum paludivagum Hitch. and Chase.—This creeping perennial is found more or less submerged in fresh water rivers and lakes in Florida, Texas, and Mexico. The material examined was tetraploid, $2n=36$ (fig. 8).

Panicum texanum Buckl.—Seed of this cultivated annual, Texas millet, supplied by Dr. D. G. Sturkie, Auburn, Alabama, gave rise to hexaploid seedlings, $2n=54$. Nielsen's (1939) count of 36 demonstrates the existence of intraspecific chromosome races in this species (fig. 9).

Panicum jubiflorum Trin. P. I. 126489.—This perennial introduction from Australia possessed 54 somatic chromosomes (fig. 10).

Panicum virgatum L.—Switchgrass, a vigorous, rhizomatous perennial, ranging from three to six feet in height when mature, is widely distributed in the prairies of the United States. The robust Florida specimen studied in this instance was octoploid, $2n=72$ (fig. 11).

Paspalum supinum Bosc.—This small perennial grows in the dry sandy open ground in the Coastal Plain from North Carolina to Louisiana. It showed 20 chromosomes in its root tips (fig. 12).

Paspalum quadrifarium Lam. F. C. 04217.—Introduced from Argentina, this robust perennial bunch grass has been one of the most frost and cold tolerant *Paspalums* grown at Tifton, Georgia. Its very poor seeding habit and lack of palatability, however, materially limit its economic value. All material examined possessed 30 somatic chromosomes (fig. 13). The high degree of sterility of *P. quadrifarium* and the fact that no species with less than 20 somatic chromosomes has been found suggest that it may have arisen recently as a hybrid between diploid and tetraploid races or species.

Paspalum intermedium Munro. F. C. 04235.—This vigorous perennial bunch grass introduced from Argentina had 40 somatic chromosomes (fig. 14).

Paspalum langei (Fourn.) Nash.—This perennial bunch grass that occurs in moist woods in Florida and near the Gulf of Mexico was found to be hexaploid, $2n=60$ (fig. 15).

Paspalum longipilum Nash.—The Florida specimen of this perennial bunch grass, which has been found in the damp sandy soils of the Coastal Plain from New Jersey to Texas, had 60 somatic chromosomes (fig. 16).

Paspalum giganteum Baldw.—This robust perennial, with short scaly rhizomes and a height of four to six feet when mature, is limited to the lower Coastal Plain of the Gulf States. The plant collected in Florida and examined in this study was duodecaploid, $2n=120$ (fig. 17).

Paspalum alnum Chase.—Commonly called Coombs *Paspalum*, this rather small tufted perennial grows in South America and Jefferson County, Texas, where it is considered an excellent pasture species. At Tifton, Georgia, however, it has failed to survive the winter. Seedling plants of this grass obtained from Texas possessed 24 somatic chromosomes that were twice the size of the other *Paspalum*

chromosomes studied (fig. 18). Thus a new basic number of either 6 or 12 for the *Paspalum* genus is suggested.

Paspalum distichum L.—Knotgrass is a widely distributed stoloniferous species that has been found growing in moist, usually warm, places of both hemispheres. A study of a large number of equatorial plates of this grass left no doubt but that the material examined possessed 48 chromosomes as the $2n$ number (fig. 19). This furnishes further evidence of the existence of a basic number of 6 or 12 in addition to the common number of 10.

Pennisetum glaucum (L.) R. Br.—Cultivated since prehistoric times in Africa and Asia for forage and human food, cat-tail or pearl millet has become a most important temporary pasture crop for cattle and hogs in several of the southeastern states. Seed to plant these temporary pastures has been produced in the Southeast for many years, yet no strains or varieties of this grass are on the market. Plants from this commercial seed usually reach a height of five to eight feet when mature and are about as variable as individuals in a commercial open pollinated variety of corn. Fourteen very large chromosomes were found in the root tip cells of a number of different seedlings of this grass (fig. 20).

Pennisetum glaucum (L.) R. Br., Russian.—In 1937 the U. S. Department of Agriculture obtained from Leningrad, Russia, several lots of seed of cat-tail millet. This seed carrying the P. I. numbers 115055 to 115059, inclusive, gave rise to plants that reached a mature height of eight to twelve feet, possessed very woody stems, were extremely heterozygous and were so late that very few matured seed the first year. A number of selections from this material are taller, woodier, later maturing and produce more leaves per stem than commercial cat-tail millet. They also seed less freely than the commercial strain. A cytological study of root tips of several of these strains revealed that they possessed 14 somatic chromosomes which seemed identical in their gross morphology with those of the smaller common cat-tail millet (fig. 21).

Pennisetum purpureum Schumach.—Introduced from Africa in 1913, this coarse perennial, commonly called napiergrass, resembles sugarcane vegetatively and reaches a height of eight to sixteen feet when mature. It has been found to be an excellent pasture plant when managed properly in a deferred system of grazing. Its cold susceptibility has restricted it to Florida and the lower Coastal Plain of the Gulf States. Several different introductions (among them P. I. 52182) and selections of this grass possessed 28 chromosomes as the $2n$ number (fig. 22).

Digitaria pentzii Stent. P. I. 77998.—Were it not for its poor seeding habits, this stoloniferous South African perennial would be a valuable pasture grass in much of the Southeast. It showed 36 somatic chromosomes (fig. 23).

Digitaria polevansii Stent. P. I. 111105.—A study of a large number of somatic complements in this

African introduction revealed 34 chromosomes as the $2n$ number (fig. 24).

Digitaria decumbens Stent. P. I. 111109.—This African introduction spreads rapidly by long prostrate stolons and does not form the tufted bunches characteristic of *D. pentzii*. It is more susceptible to winter killing than most of the *D. pentzii* introductions. Thirty chromosomes were found in the root tip cells (fig. 25).

Digitaria sp. P. I. 111128.—This South African introduction differs from the other three mentioned above by having short rhizomes, no above-ground stolons, and relatively few basal leaves. Mr. Swallen states that he has been unable to find a published description of this grass. It had 36 somatic chromosomes (fig. 26).

Axonopus affinis Chase.—The excellent seeding habits, ability to grow at low fertility levels, stoloniferous habit and tolerance of close grazing are features of this perennial which have made it, carpet-grass, well adapted to the moist sandy soils of the Coastal Plain. These characteristics are also responsible for its widespread use in improved pasture mixtures and its natural spread in many native pastures. Examination of a number of equatorial plates in the root tips of this species showed it to have 80 chromosomes (fig. 27).

SUMMARY

The somatic chromosome numbers in 27 races belonging to 26 species of the tribe Paniceae are presented.

The eleven *Panicum* species examined in this study proved to be regular members of a polyploid series having 9 as the basic number. Races of *P. anceps* and *P. texanum* were found that were higher in the polyploid series than those previously reported, demonstrating the existence of intraspecific polyploidy in those species.

Five of the eight *Paspalum* species studied occupied diploid, tetraploid, hexaploid and duodecaploid positions in a series having 10 as the basic number and extending to the hexadecaploid *P. floridanum* Michx. (1940). It is suggested that the highly sterile *P. quadrifarium*, having only 30 somatic chromosomes, arose as a hybrid between diploid and tetraploid races or species. *P. alnum* and *P. distichum*, two closely related species with 24 and 48 somatic chromosomes, respectively, demonstrate the existence of a new basic number of either 6 or 12 in the genus *Paspalum*.

Eight of the nine *Pennisetum* species reported in the literature fit a polyploid series having 9 as the

basic number. Numerous specimens of *P. glaucum* and *P. purpureum* possessed 14 and 28 chromosomes, respectively, indicating that 7 is also a basic number in this genus.

Four introductions of the highly sterile perennial *Digitaria* species from South Africa gave the irregular counts of 30, 34, 36 and 36 somatic chromosomes suggesting that some of them may be of recent hybrid origin.

Axonopus affinis collected at Tifton, Georgia, contained 80 somatic chromosomes.

THE DEVELOPMENT OF VASCULAR CONNECTIONS IN THE LEAF-SHEATH OF SUGARCANE¹

Chas. F. Moreland and Lewis H. Flint

ONE OF the characteristics of monocotyledonous plants as distinguished from dicotyledonous plants is the absence of cambium in the vascular bundle, all development arising through the differentiation of primary tissues. However, Arber (1918) has drawn attention to the rather widespread occurrence of intrafascicular cambium in this group and Artschwager (1925) called attention to cambium-like cells between the xylem and phloem of the bundles of the leaf-sheath of sugarcane. Our observations revealed vestigial cambial activity in the bundles of the leaf-sheath of sugarcane and in addition the development of an interfascicular cambium-like meristem which gave rise to cross-connecting veinlets.

Arber (1925) described cross-vascular connections between the parallel veins of the leaves of several monocotyledons. Avery (1930) described similar structures for corn, and Artschwager (1925) noted connections of the same type in sugarcane. In describing these cross-connecting veinlets none of the mentioned investigators described the way in which these connections originated.

In order to make a study of the mode of origin of the cross-veinlets, segments were obtained from the spindle of the sugarcane stalk (variety C. P. 29-320). Since the spindle consists of concentric layers of leaf-blades and leaf-sheaths of various ages surrounding the terminal bud of the stalk, segments from this region contained tissues in various stages of development. The segments were imbedded in paraffin for microtome sectioning, and sections were cut in three different planes—transverse, radial, and tangential.

Transverse sections of the spindle segments proved to be best for determining the origin of cross-connections between the vertical bundles of the sheath. Young leaf-sheaths could be found in which the primary vascular tissues were well differentiated. The protoxylem elements and the sieve tubes and companion cells of the phloem were fully developed. The metaxylem cells were in the process of maturation. Between the xylem and phloem of many of the bundles could be seen a cambium-like zone, that is, small rectangular cells arranged in radial rows (fig. 2). The parenchymatous cells between the vascular bundles were quite large and loosely arranged, with intercellular spaces between them. Occasionally within the parenchyma tissue it was noted that by a seemingly concerted activity a continuous row or chain of more or less mature parenchyma cells extending from one of the vascular bundles of the vertical system to another became meristematic and underwent an almost simultaneous internal division. This division took place in such a way that the origin of an interfascicular cambium or a cork cambium was simulated. Photomicrographs of early stages of de-

velopment are given in figures 1 and 2. It was further observed that the intervening meristematic cells connected in a tangential direction with the intrafascicular cambium of the vertical bundles involved. Thus the early stages in the development of the cross-connecting vascular tissue further suggested an interfascicular cambium (fig. 2). Of course the analogy cannot be carried very far because the interfascicular cambium of dicotyledonous stems is continuous in a vertical plane and gives rise to conducting cells of the vertical system.

The connecting veinlets were not only found connecting bundles in a tangential direction but were also observed connecting bundles in a radial direction (fig. 3). In some cases they were found to branch and connect bundles in a radial and tangential direction at the same time; that is, three bundles of the vertical system were involved (fig. 4). The branching was noted to have arisen in one original parenchyma cell. The first division of this parenchyma initial resulted in the formation of two sets of cells. Each set had its distinctive alignment.

The origin of the cross-connection veinlets was interpreted to have been of a secondary nature in that they arose from living cells that had become permanent and then returned to the meristematic condition. After the formation of the initials had taken place, the divisions which followed were in two planes at right angles to each other and parallel with the row of initials. The first two divisions appeared to be about simultaneous. Thus observations showed an initial first divided into four cells, two cells in a horizontal and two in a vertical plane (fig. 3 and 5). This was quickly followed by other divisions which resulted in the formation of about four rows of cells in each of the two planes. Thus the veinlets were about square as seen in cross section (fig. 6). The long axes of the young cells were parallel with the row of initials and their lengths were the same as the diameters of the mother cells from which they had been derived. Each group of derivatives was within the area formerly occupied by the mother cell. This regular arrangement and mode of origin indicated that the cross-connecting veinlets were composed of secondary vascular tissues.

SUMMARY

Radial and tangential cross-veinlets connecting vertical vascular bundles were observed within the leaf-sheaths of sugarcane. These cross-veinlets were distributed at approximately regular intervals in the vertical plane and were occasionally branched.

The cross veinlets originated within a single or branched horizontal line of parenchyma cells and for the most part remained restricted within the old boundaries of these cells. Temporary meristem was continuous with similar meristem within the vertical

¹ Received for publication February 2, 1942.

bundles, and differentiation extended to the elaboration of xylem and phloem.

The development of a secondary meristem and the extension of such cambium from one vertical bundle to another indicated activities within monocotyledonous plants similar to some of those more commonly associated with dicotyledonous plants.

TOMATO RINGSPOT ON CURRANT¹

E. M. Hildebrand

THE TRANSMISSION of virus diseases from woody to herbaceous plants and vice versa has been uniformly unsuccessful, according to published reports. In a borderline case, however, Smith (1937a) found that a red currant (*Ribes* sp.) developed numerous small "water-clear" lesions on the youngest leaves when inoculated by rubbing with tobacco necrosis virus. This observation was confirmed by the writer on *Ribes sativum*, and interestingly enough, aside from the initial lesions, no further pathological developments followed.

Two distinct virus diseases are now known to occur on the red currant in, respectively, the northeastern United States (Hildebrand, 1939) and Germany (Winter, 1940). Efforts at transferring the American currant mosaic disease from plant to plant by mechanical methods have always been unsuccessful.

At the Rockefeller Institute in 1939-40, during an investigation aimed at the discovery of the insect vector of currant mosaic, diseased currant plants were grown under different temperature conditions to study the effect on the insects harbored by the plants. Typical currant mosaic symptoms (fig. 1) developed only on the plants incubated at the lowest temperature range (60°-70°F.). The plants held at the higher temperatures failed to develop chlorosis either in the greenhouse during the winter or spring or after transplanting outdoors for the remainder of the 1940 season. Proof that the virus symptoms had been masked by high temperatures was obtained when the plants under consideration again exhibited typical chlorosis in the outdoor planting in 1941.

In early February, 1940, during one of the frequent examinations made of the plants which failed to develop chlorosis, peculiar chlorotic ring patterns (fig. 2) were noted on occasional young leaves in the 70°-80°F. greenhouse. The zonate chlorotic spots which ordinarily failed to persist when the leaves matured had not been seen hitherto on the currant and suggested the presence of another virus disease

¹ Received for publication February 4, 1942.

This study was initiated and the greater portion of it carried out in the Plant Pathology Division of the Rockefeller Institute for Medical Research at Princeton, N. J., while the writer held a John Simon Guggenheim Memorial Foundation Fellowship during 1939-1940.

in addition to currant mosaic. Because of their shape the spots aroused suspicion as to a possible relationship to several well known ringspot-virus diseases and invited an attempt to transmit the disease by mechanical methods.

The present report is concerned with this new virus disease of currant, its transmission by mechanical means to tobacco, and its identification as a strain of tomato ringspot virus (*Annulus zonatus* H., Holmes, 1939). Studies on its possible relationship to the mosaic disease with which it was associated in currant have not been concluded.

TRANSMISSION EXPERIMENTS FROM CURRANT TO TOBACCO.—The first transmission experiment conducted in February, 1940, when occasional leaves of the new growth on currant were beginning to show distinctive ringspot symptoms, gave rise to zonate necrotic lesions on tobacco, proving that a sap transmissible virus was present in the currant. Two or more plants of each of the following species—*Nicotiana tabacum* L. var. Turkish, *N. rustica* L., *N. glutinosa* L., *N. langsdorffii* Weinm., *N. sylvestris* Speg. and Comes, China aster (*Callistephus chinensis* Nees.), cowpea (*Vigna sinensis* (L.) Endl. vars. Black and Blackeye), bean (*Phaseolus vulgaris* L. var. Early Golden Cluster), Wilder red currant (*Ribes sativum* L.), and tomato (*Lycopersicon esculentum* Mill. var. Bonny Best)—were inoculated by the rubbing method with fresh juice extract, in all cases at least one plant being dusted with carborundum beforehand. On the seventh day, three ringspot lesions were observed on a Turkish tobacco plant and twenty-one and twelve lesions, respectively, on two *N. rustica* plants all of which had received the carborundum treatment. About twenty of the lesions were removed with a cork borer and used for sub-inoculating *N. rustica*, *N. glutinosa*, China aster, and Turkish tobacco, one lesion to the plant. Abundant ringspot lesions appeared in all inoculated plants of Turkish tobacco and *N. rustica*. In one out of two cases infection resulted on aster. Although distinct symptoms did not develop on plants of *N. glutinosa*, transmission experiments demonstrated that they contained the virus.

Returning to the masked mosaic diseased currants at intervals of about one week, seven successive trials

were attempted from the original and subsequent consignments of plants brought indoors from the Hudson Valley source, with similar positive results in six cases. All six isolation experiments with leaves from healthy plants obtained from a New York nursery gave negative results. The fact that juice extract from mosaic diseased currants from two other sources (New York and New Jersey) in six different trials failed to induce the ringspot disease on tobacco indicated rather definitely that, since the ringspot disease was not always associated with the mosaic disease, it was in all probability a chance contaminant and a distinct new disease of the currant.

TRANSMISSION EXPERIMENTS FROM TOBACCO TO CURRANT.²—Transmission of the ringspot virus from tobacco back to currant by mechanical means has not been accomplished thus far. The virus content of the expressed juice from infected tobacco plants which was employed was between 100 and 1,000 times as great as that of juice from currant. Various devices such as rubbing, needle-pricking and injection seemed to be equally ineffective. Such variations in methods for inoculating currant plants as rubbing with and without carborundum, rubbing the upper and lower leaf surfaces, inoculating different-aged leaves, the use of juice diluted and nondiluted, and of juice with and without buffer, inoculation at different hours of the day, employing several types of needle puncture, injection into the stems with a syringe, and the use of plants of different ages and sizes, all proved ineffective for reproducing the ringspot symptoms. Details of these mechanical transmission tests, which involved forty experiments and over 200 currant plants have been omitted because the results have always been negative.

IDENTIFICATION OF CURRANT RINGSPOT VIRUS.—*Transmission experiments.*—Sap transmission from tobacco to tobacco and from the various susceptible plants back to tobacco was readily accomplished by the rubbing technique. The number of lesions was increased about ten-fold by first dusting with carborundum powder. The zonate necrotic spots on Turkish tobacco were similar in appearance to those produced by tomato-ringspot virus (Price, 1936; Holmes, 1939); similar to, but distinct from, those produced by tobacco-ringspot virus (Price, 1936); and distinct from those caused by the tomato-ringspot virus described by Imle and Samson (1937). The spots had begun to appear by the second day

² One of the problems encountered in these studies was that of securing suitable small currant plants for transmission experiments. Cuttings taken in the fall produced roots and a few leaves but could not be used because they proved to be partially dormant. Cuttings started in March, 1940, rooted readily and produced excellent plants. The commercial rooting stimulant, Hormodin No. 1 powder, proved effective for speeding up root production. Three weeks from the time the cuttings were made slightly over 90 per cent of those which received the stimulant as compared to about 9 per cent of the untreated ones were well rooted and ready for potting. The untreated cuttings required about twice as long for good rooting. The same procedure was used again in the 1941 studies but with less striking results from the rooting stimulant.

following inoculation. Similar systemic lesions appeared later. Upon reaching the systemic stage the subsequent plant growth was symptomless. Such plants had apparently developed what has been called specific, non-sterile immunity and were found not susceptible to reinfection.

Influence of buffers on infectivity.—Mixing infective juice extract from tobacco with a buffer solution (0.1 M. phosphate buffer, pH 7.0) failed to increase infectivity. For example, in one experiment at a dilution of 1:10 the average number of lesions per plant with buffer was 46 as against 71 lesions where distilled water was used. In another experiment the two treatments gave practically identical results of 48 and 56 lesions.

Influence of age of plant on susceptibility.—In general, the very young plants were much more susceptible to infection than the older ones. The currant ringspot virus was found to be of relatively high concentration in young plants of nearly all species found susceptible to infection. Young *Nicotiana rustica* plants were much more susceptible than older ones, and as many as 50 per cent died in some tests. With pokeweed, age of plant seemed to make little difference in susceptibility. Pokeweed and cowpea plants largely failed to survive infection. Only tiny tomato plants between two and three inches tall were readily inoculated. The appearance of concentric zonate necrotic spots was followed by extreme stunting (fig. 4), abnormal string-like growth of the leaves, and failure to bear fruit. While the virus became systemic in several of the susceptibles. Turkish tobacco was employed as test plant in the immunization studies discussed later.

HOST RANGE.—The host range of the currant-ringspot virus, as far as it has been determined, closely agrees with that of tomato ringspot (Price, 1940a). The following plants, taken at random from the list tested by Price, have been found susceptible, in all cases the virus being reisolated from the inoculated plants: *Amaranthaceae*—*Amaranthus caudatus* L.; *Apocynaceae*—*Vinca rosea* L.; *Caryophyllaceae*—*Lychnis chalconica* L.; *Chenopodiaceae*—*Beta vulgaris* L.; *Compositae*—*Callistephus chinensis* Nees., *Helianthus annuus* L., *Zinnia elegans* Jacq.; *Crassulaceae*—*Sedum acre* L.; *Cruciferae*—*Lobularia maritima* Desv.; *Cucurbitaceae*—*Cucumis sativus* L.; *Euphorbiaceae*—*Ricinus communis* L.; *Geraniaceae*—*Pelargonium hortorum* Bailey; *Gesneriaceae*—*Sinningia speciosa* Benth. and Hook.; *Hydrophyllaceae*—*Nemophila insignis* Benth.; *Labiatae*—*Coleus blumei* Benth.; *Leguminosae*—*Phaseolus vulgaris* L. var. Early Golden Cluster, *Vigna sinensis* Endl.; *Phytolaccaceae*—*Phytolacca decandra* L.; *Polemonaceae*—*Phlox drummondii* Hook.; *Resedaceae*—*Reseda odorata* L.; *Saxifragaceae*—*Ribes sativum* Syme. var. Wilder; *Scrophulariaceae*—*Cymbalaria muralis* Gaertn., Mey. and Scherb.; *Solanaceae*—*Lycopersicon esculentum* Mill. var. Bonny Best, *Nicotiana glutinosa* L., *N. langsdorffii* Weinm., *N. rustica* L., *N. sylvestris*

Speg. and Comes, *N. tabacum* L. var. Turkish, and *Solanum nodiflorum* L.

CROSS IMMUNIZATION.—Cross-immunization experiments with two other ringspot viruses have resulted in protection only against tomato ringspot, suggesting a close relationship to this virus. The mechanism of acquired immunity in plants and the procedure for obtaining plants for cross-immunization studies have been discussed in detail by Price (1940c). Briefly, the procedure depends on the fact

that small inoculated plants recover from the disease symptoms while still containing the virus. Cuttings made from these plants and rooted in a mixture of peat and sand were ready for use in about six weeks from the time the inoculations were made and, except for a slight loss in vigor, were normal in appearance.

When inoculated with the currant ringspot virus, typical symptoms were produced on the plants immunized against tobacco ringspot, on healthy seed-

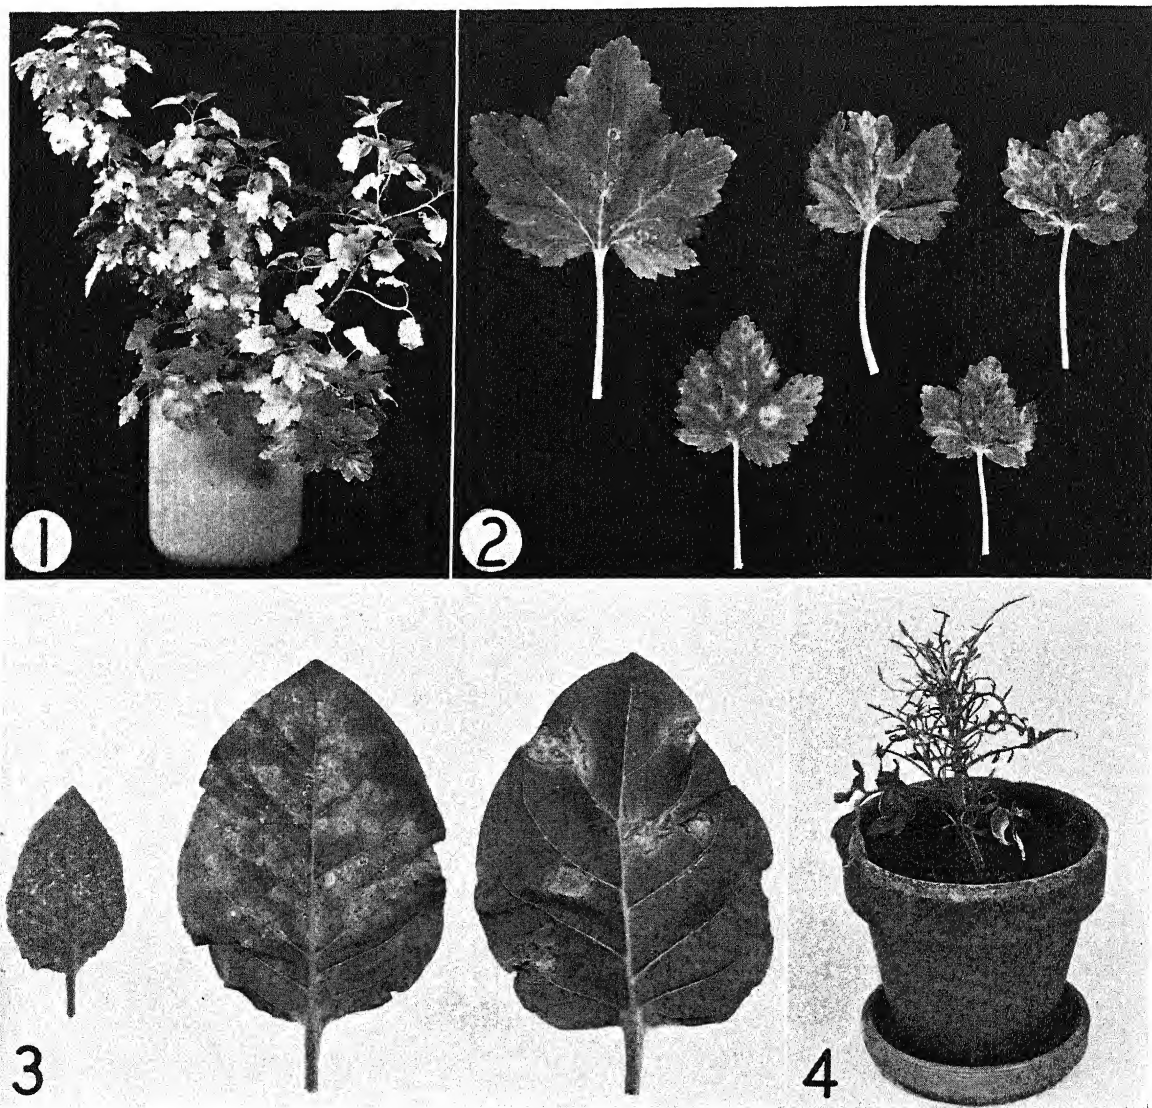

Fig. 1-4.—Fig. 1. Plant affected with an advanced stage of currant mosaic. This plant was dug up from a currant planting in the vicinity of Princeton, New Jersey, and was much stunted in comparison with neighboring healthy plants.—Fig. 2. Symptoms consisting of zonate chlorotic spots occurring on occasional leaves of mosaic diseased currant grown in a greenhouse held between 70° and 80°F. At this temperature currant mosaic symptoms failed to appear. This symptom has not been observed in the field.—Fig. 3. Symptoms consisting of zonate necrotic spots are characteristically produced on Turkish tobacco by the currant strain of tomato ringspot virus. The small leaf on the left shows systemic lesions, while the other two on the right show typical lesions when many or few are produced on tobacco leaves.—Fig. 4. Tomato plant severely stunted by currant ringspot virus as the result of inoculation when about three inches tall. This photograph was made five weeks after inoculation. (Photographs by J. A. Carlile.)

lings, and on rooted cuttings from healthy seedlings, but no symptoms occurred on the plants immunized against tomato ringspot. This test was repeated twice with identical results. Usually four plants falling into each category were employed in each experiment.

Reciprocal tests using plants which had recovered from the currant ringspot virus always gave symptoms when inoculated with tobacco ringspot but showed protection when inoculated with both tomato-ringspot and the currant ringspot viruses. Based on preliminary experiments on virus concentration in juice extract the plants immunized against the currant virus were found to contain approximately as high a virus content as plants with symptoms before recovery; however, this point has not been precisely determined. These tests furnish what is considered conclusive proof that the virus isolated from currant is very closely related to tomato-ringspot virus. Because of its greater virulence it is considered not exactly identical with, but a strain of, the tomato-ringspot virus.

Thermal inactivation.—The currant-ringspot virus became inactivated after an exposure of ten minutes at approximately 60°C. (table 1). The procedure and apparatus for making these determinations were those of Price (1940b). Both Turkish tobacco and the Black variety of cowpea were used for test plants. The two primary leaves of each of eight cowpea plants and of each of four Turkish tobacco plants were inoculated with a single virus sample. Inoculations were made by rubbing a cheesecloth pad soaked in the virus sample on the upper surface of test-plant leaves previously dusted with carborundum. Because the injury caused by carborundum interfered with making readings on the cowpea, these data were omitted from the table.

In a preliminary experiment on thermal inactivation it was found that the fresh virus extract from tobacco failed to survive exposures of one to seven minutes in a water bath held at 70°C. but survived a 55°C. temperature at all intervals up to and includ-

ing thirty-five minutes, the longest period tested. Ten-minute exposures inactivated the virus between 60° and 75°C. but not at 55°C. and below. The second thermal inactivation experiment gave confirmatory and more precise results (table 1). These results agree closely with those of Smith (1937b) for the tomato-ringspot virus, who found that it was inactivated by a ten-minute exposure in water held at 60°C. but not by ten minutes at 55°C.

Dilution end point.—The dilution end point of juice freshly extracted from diseased tobacco was approximately 1:1,000, or slightly above, but never reached as high as 1:5,000. Three dilution end-point experiments were conducted and in every case lesions were obtained on the test plants from the 1:1,000 dilution but never from the 1:5,000 or 1:10,000 dilutions, the number of lesions per test plant averaging three. This concentration of virus averages slightly lower than that usually obtained from diseased currant plants.

Resistance to aging.—The currant-ringspot virus resists between three and four days' exposure in extracted sap at room temperature and a period of longer than one month when held in a mechanical refrigerator maintained at approximately 5°C. For example, one 29-day-old sample held in the refrigerator produced between ten and fifteen lesions per test plant, whereas part of the same sample kept at room temperature had completely lost activity at the end of four days.

The virus in infected leaves resisted freezing and retained activity for at least three weeks when stored in the frozen state.

Passage through a Berkefeld filter removed between three-fourths and nine-tenths of the activity of the virus, based on the local-lesion count on Turkish tobacco.

As a result of the above studies it has been concluded that the strain of ringspot virus isolated from the currant is the same as, or closely related to, that of tomato ringspot.

DISCUSSION.—It is of considerable interest that previous to this study the tomato-ringspot virus had not been found in nature, having appeared on tobacco in the greenhouses at Princeton in the spring-time as a contamination on tobacco presumably brought in by an insect vector. Doubtless there must be wild hosts which are far more important as reservoirs of this virus than the currant. The fact that a virulent strain of tomato ringspot virus was obtained by mechanical means from some and not from other currant plants affected with mosaic definitely indicates that two entities were involved. Failure to transmit the ringspot virus back to the currant by mechanical means may be due to the fact that present methods are inadequate for inoculating currants with viruses or that the insect vector alone is capable of performing such transmissions. This phase of the problem deserves and is receiving additional attention.

SUMMARY

A virus has been recovered in the juice extract from currants which produces a disease on tobacco practically identical to tomato ringspot (Holmes, 1939). This currant-ringspot virus is considered a strain of tomato-ringspot virus, because it agrees with the latter in all important particulars, with the possible exception of being more virulent.

Cross-immunization tests with other ringspot viruses have resulted in protection only against tomato ringspot.

The host range, as far as tested, closely agrees with that of tomato ringspot. Likewise, there is close agreement in other details, including incubation period, thermal inactivation, longevity *in vitro*, filterability, and dilution end-point.

This appears to be the first case of mechanical transmission of a virus from a woody plant to tobacco, but unfortunately thus far it has not been

possible to return the virus to the currant by mechanical means.

Since it has been found that the ringspot virus can be obtained from some and not from other currant plants affected with mosaic, it is tentatively concluded that two entities are involved, currant mosaic and tomato ringspot.

COMPETITION OF WESTERN WHEAT GRASS WITH RELICT VEGETATION OF PRAIRIE ¹

J. E. Weaver

MANY PROFOUND changes in mid-continental grasslands have resulted from the recent extended drought. In the prairies of eastern Nebraska, Kansas and South Dakota, the earlier continuous stands of bluestem (*Andropogon scoparius* and *A. furcatus*) have often been greatly fragmented and now occur as relict patches a few square feet to many square rods in extent. Loss of approximately 95 per cent of little bluestem has left the prairie cover very open. Over large areas, except for weeds and a few surviving grasses and forbs, the soil was bared (Weaver, Stoddart and Noll, 1935; Weaver and Albertson,

1939). Grasses more xerophytic than the bluestems have greatly increased, notably needle grass (*Stipa spartea*), prairie dropseed (*Sporobolus heterolepis*) and western wheat grass (*Agropyron smithii*). The wheat grass has entirely replaced other grasses in many prairies and is such a vigorous competitor for water that its invasion into countless relict areas of weakened bluestems has gradually resulted in their disappearance together with most of the accompanying forbs.

It is the purpose of this paper to discuss the ecological characteristics of western wheat grass, to describe the effects of its competition with relict prairie vegetation, and to present experimental data which show that this grass profoundly modifies the water relations of prairie soil.

¹ Received for publication December 16, 1941.

Contribution from the Department of Botany, University of Nebraska, No. 134.

This study was made with the aid of a grant from the Penrose Fund of the American Philosophical Society.

GROWTH HABITS AND ECOLOGICAL CHARACTERISTICS.—Western wheat grass (*Agropyron smithii*, Rydb.) is a perennial, sod-forming grass with abundant rhizomes. The rigid, erect stalks vary from 1 to 5 feet in height, depending upon soil fertility and water supply. Stems arise singly or in small numbers from the nodes of the rhizomes, which are usually 1 to 3 inches apart. When the stalks have developed the spikes, which are 2 to 6 inches long, the plants give the mass effect of planted stands of wheat (fig. 1). The rigid, upright, bluish green leaves vary from 4 to about 12 inches in length. They are deeply ridged above and roll tightly inward during periods of drought. Where seasonal moisture is plentiful, the stems grow thickly, often 1,200 or more per square meter, and the sod is compact.

Growth is renewed in true prairie early in spring. The time varies with the season, but it is three to six weeks before the middle of April, in eastern Nebraska, at which time new shoots of little bluestem (*Andropogon scoparius*), big bluestem (*A. furcatus*), side-oats grama (*Bouteloua curtipendula*), and most other grasses begin to appear. A height of 6 to 10 inches is often attained by April 15. Vegetative growth is usually complete and spikes are produced during June, at least on dry years. Maturity is normally attained by mid-July. If the soil becomes dry, western wheat grass is dormant until fall rains stimulate new growth. Otherwise, the leaves remain green and active. Under grazing, growth occurs usually throughout the summer. Since the grass is of northern extraction, it remains green and develops vigorously even late in autumn.

Seed is produced abundantly in true prairie, but the plants also spread widely by means of rhizomes. These are 0.5 foot to more than 3 feet long, much branched, and grow very rapidly. The growth periods of rhizomes are correlated with those of tops. They exhibit great resistance to desiccation (Mueller, 1941).

The roots of *Agropyron smithii* develop rapidly and penetrate deeply. Seedlings near Lincoln, Nebraska, produced roots which extended to a depth of 2.5 feet when three months old (Clements and Weaver, 1924). Many of the roots of mature plants penetrated moist upland prairie soil to a depth of 8 to 9 feet (Weaver, 1920). In the drier soil, the surface absorbing system was much better developed. Numerous, short, horizontal roots arose from the bases of the plants and from the rhizomes. These were profusely branched and rebranched to the fourth order, the ultimate branches being almost microscopic in size and furnishing a good surface absorbing system (Weaver, 1919). Here, most of the roots did not exceed 5 to 6 feet in depth.

Because of the persistence of the rhizomes even under cultivation, western wheat grass is usually the first perennial grass to appear in quantity on abandoned dry-farm lands (Judd and Jackson, 1939; Tolstead, 1941). It is also an early invader, frequently the first, into soils that have drifted over other vegetation causing its death. It may extend up-

ward through a layer of 5 to 10 inches of wind-blown soil.

Increase in abundance of this species was one of the most striking phenomena of the drought (fig. 2). Extensive earlier studies in the prairies of eastern Nebraska, Kansas, and South Dakota (Weaver and Fitzpatrick, 1934) have shown that western wheat

Fig. 1. Characteristic stand of western wheat grass as it appeared in July. The foliage is about 18 inches tall and the flower stalks about 2.5 feet. Photo. by W. L. Tolstead.

grass constituted an almost negligible part of this grassland. Usually it occurred only where there had been some disturbance.

EFFECTS OF COMPETITION ON OTHER GRASSES AND FORBS.—Outcome of competition of wheat grass with other species for water is shown not only in their wilting and dwarfing but also often by their death. Retardation in growth was so common and so striking that numerous measurements were made of the height of the same species growing within areas dominated by western wheat grass and a few feet distant in areas of relict prairie grasses. Average heights in June, 1938, were as follows: tall dropseed (*Sporobolus asper*) 10 and 14 inches, big bluestem 7 and 11 inches, side-oats grama 6 and 7 inches, prairie dropseed 8 and 12.5 inches, and needle grass 13 and 17 inches. Similar differences were found in many prairies; often the suppressed plants were wilted and drying. Usually needle grass was not found with western wheat grass, but where it did occur its flower stalks were frequently reduced to 1 to 6 per plant. June grass (*Coeleria cristata*) was affected in a similar manner (fig. 3 and 4). The mesic Kentucky blue grass, which still grew as a drought

Fig. 2. Northeast hillside of former bluestem prairie near Lincoln, Nebraska, now completely dominated by western wheat grass. July 19, 1940.

relict in bluestem prairie, was never found under wheat grass.

That competition for water was also severe between the individual plants of wheat grass was shown by their growth in dry years. They headed sparingly where this grass had occupied the soil for

several summers, but in adjacent, newly invaded territory where the stems were fewer and competition for water less severe they formed spikes and produced abundant seed. Where western wheat grass was best developed in typical prairies in 1940, the foliage was 22 inches tall and flower stalks 36 inches

Fig. 3-4.—Fig. 3 (left). Needle grass 13 inches tall growing with western wheat grass near Crete, Nebraska, and a bunch 30 inches high growing a few feet distant without similar competition. The first had dried without producing seed. June 15, 1940.—Fig. 4 (right). Much dwarfed June grass growing with western wheat grass (center) and bunches a few feet distant from prairie uninvaded by wheat grass. June 15, 1940.

high. This contrasted sharply with other, older alternates where the height of the grass was only 15 inches and the flower stalks, if any, were only 22 inches tall.

Even casual observation revealed a striking decrease in number of forbs just as soon as one entered an area dominated by western wheat grass.² Smooth goldenrod (*Solidago glaberrima*) and many-flowered aster (*Aster multiflorus*) have been unusually abundant since the drought, but where they have been invaded by western wheat grass, both have occurred as scattered single-stemmed individuals, or have formed very open patches much reduced in height. Many deeply rooted forbs, such as *Psoralea floribunda*, have been found to be smaller in size in areas of wheat grass, and to have a greatly reduced number of blossoms.

Decrease in both species and numbers of forbs was ascertained in several prairies by counting the perennial forbs in circular areas 50 feet in diameter. These circles were located at random, usually two in patches of wheat grass and two in the prairie grasses where invasion had not occurred. Since it was impossible to determine individual plants of many species with branched rhizomes, and since suppressed plants usually had fewer stems than vigorous ones, the number of stems rather than the number of plants was counted. This could be done accurately by separating the circle into small sectors and examining each individually.

The results of this survey showed that in every sample both the number of species and the number of stems was much lower in areas occupied by wheat grass. Number of species of perennial forbs in western wheat grass varied from 7 to 11 per circle (1,963 sq. ft.) with an average of 9. In areas occupied by other grasses the number ranged from 11 to 24 with an average of 16. The average number of stems in the same sequence was 748 and 3,831, respectively. The largest number of stems in any circle in western wheat grass was 1,566. This was somewhat more than half of the smallest number of stems (2,733) found in any circle in the bluestem grasses. This extensive survey of forbs revealed that competition of wheat grass had reduced the number of species to 56 per cent of those remaining in bluestem and the number of stems to approximately 20 per cent.

Single stems of old plants were frequently found in the wheat grass. These included *Baptisia leucophaea*, *Echinacea pallida*, *Kuhnia glutinosa*, *Petalostemon candidus*, *Psoralea argophylla* and *P. floribunda*. Species most commonly found and with the largest number of stems were *Amorpha canescens*, *Liatis punctata* and *Aster multiflorus*. But even these deeply rooted xeric forbs were often greatly dwarfed, wilting, or dying in the wheat-grass sod.

DRYING OF THE SOIL.—Western wheat grass, by its early and vigorous development, may absorb from

² Loss of forbs has been very high in all grassland west of the Missouri River (Weaver and Albertson, 1939, 1940). The losses have increased with each succeeding year of drought. They will be discussed in a separate paper.

the soil all available water. During years of low precipitation this may occur before later growing species produce much new growth. They can then develop only slowly if at all, depending upon the current rainfall. Moreover, even in good, uniform stands of western wheat grass, the soil surface may be almost without debris. In much of the wheat-grass prairie, the bare soil is exposed directly to sunshine, the shade pattern covering less than one-third of the surface at 10 A.M. At best, only about one-third of the soil is protected by a thin layer of debris and water loss by evaporation directly from the soil is high. The losses by transpiration and evaporation rapidly reduce available water content. Moreover, direct loss of rainfall by runoff is high, since rate of water infiltration is low. These conditions have been repeatedly shown by soil sampling, by field tests on rate of water infiltration, and by experiments on time and amount of water absorption by western wheat grass and other grasses.

Field tests of soil moisture.—Western wheat grass invaded the prairie near Lincoln that has been used several years for experimental studies (Fredricksen, 1938; Noll, 1939). By 1937 it had become well established in numerous large patches. This grass had so depleted the soil water during the dry spring and early summer of 1938 that by July 21 the leaves were rolling and some were beginning to dry. Outside these places the bluestems and other grasses, which resumed growth much later, were unwilted and growing vigorously. Soil samples were taken in duplicate in places occupied by western wheat grass and bluestems, respectively. The pairs of samples within and without the western wheat-grass alternates were taken only 9 feet apart. The soil in any pair of samples was so similar that no difference except that of water content could be found. The excess water content of the soil covered with bluestem prairie over that clothed with western wheat grass is shown in table 1. There was always a higher water content, often 3 to 8 per cent higher, in the bluestem prairie.

TABLE 1. Percentage of water, based on dry weight of soil, in prairie with bluestem vegetation in excess of that in the western wheat-grass type.

Depth, ft.	July 21, 1938			May 2, 1941		
	Sta. 1	Sta. 2	Sta. 3	Sta. 4	Sta. 5	Sta. 6
0 -0.5.....	4.7	3.1	1.3	11.4	2.3	5.2
0.5-1.....	3.6	5.1	4.4	10.5	2.4	2.1
1 -2.....	3.7	7.9	9.2	13.0	2.4	5.1
2 -3.....	4.8	8.1	4.6	10.7	6.4	10.0
3 -4.....	5.8	8.7	2.8	10.4	5.9	6.9

Samples were also taken on May 2, 1941, just within and outside of three different alternates of western wheat grass in the same prairie. Since 1938, however, all of the wheat-grass alternates had greatly extended their area. The depths of moist soil in inches in bluestem prairie and in western wheat grass in the three sets of samples were 48 and 22; 32 and

23; and 47 and 23 inches, respectively. At greater depths the soil moisture was nonavailable, and the grass roots were dead. The samples again showed consistently smaller amounts of water in the wheat-grass soils, often 5 to 10 per cent less (table 1). These examples are representative of many others; at every sampling throughout several seasons the soil under wheat grass was always drier than under the less xeric prairie grasses.

Fig. 5. (Upper.) Development of grasses on April 25. New shoots of *Andropogon scoparius* (left) average an inch in height but only half of the sod is green. Western wheat grass (right) is 7 inches tall and in the fourth-leaf stage. (Lower.) Development on May 20. Little bluestem is only 6.5 inches tall; western wheat grass is 20 inches high and in the eighth-leaf stage; the spikes are just appearing.

Experiments on water infiltration.—The rate at which water enters prairie soil has been shown experimentally to be determined largely by the cover of grass and debris. Cover prevents loosening of the soil by the impact of the water and carrying of the finer soil particles into the soil pores, thus more or less closing them near the soil surface. On soils bared by drought and then invaded by western wheat grass, intake of water may be reduced by the formation of a thin, dense, compact layer on the surface (Duley and Kelly, 1941). The rate of entry of water was determined for soil covered with bluestem or other predrought native grasses and for the same soil clothed with western wheat grass. In these experiments, steel cylinders, one square foot in cross-sectional area and 4 inches long, were used. The cylindrical wall was only 2 mm. thick, and the steel was sharpened; hence, when it was oiled it

could easily be forced vertically into the soil without disturbance to soil structure to a depth of 3.75 inches. Water was then added, as rapidly as it could be absorbed, from a sprinkling can with small perforations until a total of one gallon had been applied. The time for the infiltration of the water was recorded. Data were obtained from eight widely separated prairies; the first six were in southeastern Nebraska and the last two in north-central Kansas. All were on soils of silt-loam texture. The pairs of experimental areas were never more than 9 feet apart and sometimes only 6 feet. Prairie grasses were predominantly big bluestem (table 2).

TABLE 2. Minutes required for the infiltration of one gallon of water sprinkled slowly on one square foot of soil covered with (P) predrought prairie grasses or (W) western wheat grass.

Station	P	W
Lincoln	6.5	30.0

Clay Center	5.5	10.5
Montrose	5.0	12.5
Belleville	8.5	11.5

The time of infiltration of water was consistently much greater in western wheat grass. The average time was 6.4 minutes where a stand of prairie grasses was present and 15.3 minutes where western wheat grass clothed the soil. Thus, the rate of infiltration was 2.4 times as rapid in normal prairie as in western wheat grass. This accounts in part for more moist soil in undisturbed prairie and drier soil in wheat grass. Similar differences in depths of water penetration after rains have been repeatedly observed.

In another experiment at Lincoln, Nebraska, water was added to two separate plots of predrought prairie grasses, each 3×5 feet in area, and two adjacent ones of western wheat grass on nearly level land. Six-inch boards were placed on edge, 5 inches deep, firmly around each plot to prevent runoff. Water was added to the dry soil from sprinklers for 1.5 hours as rapidly as it was absorbed. Average absorption in the bluestem plots was equivalent to 7.27 inches of rainfall, that in the wheat-grass plots amounted to only 2.98 inches. Soil in the undisturbed prairie was wet to an average depth of 29 inches at the end of the experiment; that under wheat grass to only 10.4 inches. This again illustrates the degree to which infiltration of water into soil covered with wheat grass is retarded.

Experiments on water loss.—Early in the spring of 1941, large blocks of sod of western wheat grass and little bluestem were secured in single pieces to a depth of 10 inches. They were circular in area and

just large enough to fit into galvanized iron containers 18 inches in diameter. These containers, which were 24 inches deep, had previously been filled to within 12 inches of the top with well tamped, fertile, silt-loam soil of optimum water content. Two sods of each species were transplanted, care being taken to maintain the natural surface mulch. Soil was packed firmly about them so that after moistening no water was lost through spaces which might have occurred had the soil shrunk from the wall of the container after transplanting. The soil level was 2 inches below that of the top of the container, thus permitting absorption of rainfall without runoff. The containers were placed out-of-doors in a frame of two-inch planks, the interspaces between containers and frames being filled with insulating material. The initial water content was approximately maintained by restoring the containers to their original weight by the addition of water at each of the 6 weighings (or oftener if necessary) between March 25 and May 20. Water received directly from rainfall was measured by means of a rain gauge placed beside the containers.

Spring was very late and cool. Western wheat grass began growth on April 1 but little bluestem remained dormant until April 15. Some water, of course, was lost by direct evaporation even from the containers of dormant little bluestem (fig. 5).

The greater loss of water (*i.e.*, transpiration plus evaporation) from the early maturing western wheat grass compared with that lost from little bluestem was very marked. That from wheat grass was 86.65 pounds, which was more than twice as much as that from little bluestem, 41.55 pounds. Experiments in prairie at Lincoln, Nebraska, during the preceding spring are in accord with these findings (R. J. Weaver, 1941).

Rapid development in early spring and early maturity is an excellent method of evading summer drought. Consequently, western wheat grass competes very successfully with prairie grasses of later growth, especially during years of low rainfall.

ROOT DEPTH DURING DROUGHT.—The depth of the root system of western wheat grass was examined at numerous stations near Lincoln in 1941, as was also the depth of big bluestem growing near it. Usually a single trench 7 to 8 feet long permitted the examination of both species. A layer of subsoil 1.5 to 3 feet thick and beginning at a depth of 2 to 3 feet had been without available water over a period of several years. The spring of 1941 was one of rather high rainfall, however, and the surface soil to a depth of 2 to 3 feet had been well moistened. On May 30 and 31, the roots of wheat grass reached a depth of only 24 inches, below which the silt-loam soil was without water available to growth. Roots of big bluestem, 3 feet distant, extended to the depth of moist soil which was at 33 inches. In another excavation, also in silt-loam soil, maximum root depths were at 24 and 48 inches, respectively. In a trench excavated in a third prairie, the maximum depth of the extremely dense network of wheat-grass roots was 30 inches,

but that of big bluestem and certain forbs was 50 inches. That little and big bluestem and prairie forbs had been the former occupants was clearly revealed by the abundance of their dead and partially decayed roots which were found intermixed with those of the living wheat grass but which also occurred in the dried soil two or more feet below the wheat grass.

Despite the shallowness of soil moisture, western wheat grass was in excellent condition. The foliage was 20 inches high and the flower stalks 10 to 12 inches taller.

PRACTICAL SIGNIFICANCE.—Western wheat grass has a much lower forage value in true prairie and in native pastures originating from true prairie than the better forage grasses which it is able to suppress or which often die as a result of competition for the limited water supply during drought. Hence, its tendency to form pure stands or a nearly pure growth at the expense of most other species creates a serious economic problem. Only two native grasses compete successfully with it. Side-oats grama has done so only when early spring was dry and late spring and summer moist. Blue grama is more drought resistant than western wheat grass. It successfully invades pure stands of this grass and may gradually replace it. But blue grama is a short grass and yield is relatively low.

SUMMARY

Agropyron smithii is a common sod-forming, perennial, forage grass of midwestern prairies. It is so successful a competitor for the meager supply of soil moisture that it often causes the death of more mesic grasses and forbs of the true prairie. It renews growth in early spring, produces abundant foliage which normally reaches a height of 1.5 to 2 feet in June and is overtopped by flower stalks 1.5 to 2 feet taller. Seed is produced in abundance, and migration is rapid by means of long, slender, much branched rhizomes. Formerly occurring sparingly in the eastern portions of Nebraska and Kansas, western wheat grass spread rapidly and widely following the great deterioration of grassland due to drought.

The early luxuriant growth, when water was available, resulted in greatly reducing the amount of soil moisture for use by other species, most of which began development four or more weeks later. Lack of much debris under western wheat grass permitted rain to loosen the surface soil and roil the water that entered it. This resulted in decreased infiltration and greater runoff than on soil covered with bluestems. Amount of water transpired from a normal stand of western wheat grass or evaporated from the soil it covered was more than twice as great from March 25 to May 20 as that from little bluestem prairie.

Normal root depth in moist soil is about 8 feet; during the drought the depth corresponded with depth of moist soil which was about 2 to 2.5 feet. A few feet distant, higher water content and much deeper penetration of both water and roots of other grasses were recorded.

Competition for water resulted in great dwarfing and often in wilting and death of most other prairie grasses and forbs. Numbers of species and numbers of stems of perennial forbs were greatly decreased after western wheat grass once became thoroughly established. In prairies on silt-loam soil and under similar precipitation, the number of perennial species of forbs was only 56 per cent as great in wheat grass, and the number of stems 20 per cent of that in uninvaded areas.

The large area of drought-damaged true prairie and native pasture now dominated by western wheat grass and the harmful effects of the successful competition for water of western wheat grass with species of greater forage value present a problem of much scientific interest and great economic importance.

THE LIGHT-CONTROLLED DIURNAL RHYTHM OF ASEXUAL REPRODUCTION IN *PILOBOLUS*¹

David L. McVickar

FOR OVER two and one-half centuries botanists have been interested in *Pilobolus*. They have investigated this delicate coprophilous representative of the Mucorales in relation to its taxonomy, morphology, phototropism, and periodicity. However, only the first three aspects have received detailed treatment. The most striking property of *Pilobolus*—rhythmic asexual reproduction—has not been accorded careful study.

It will be evident from the survey of literature to follow that little more is known concerning this periodicity than that it is effected by, or at least influenced by, the alternation of day and night. Most of the knowledge thus far acquired has been incidental to study of other aspects of the behavior of *Pilobolus*, particularly the influence of light on sporangiophore development. Past investigators have not examined

the periodicity directly, possibly because the technique of growing *Pilobolus* in cleared nutrient agar was not perfected. Since this culture method greatly extends the possible range of experimentation, a reopening of the problem of periodicity of asexual reproduction in *Pilobolus* seems justified. This paper (1) presents evidence that periodicity is wholly dependent upon daily alternating periods of light and darkness, and (2) contains observations indicating an experimental approach to the problem of the mechanism controlling periodicity.

HISTORICAL BACKGROUND.—The earliest known reference to *Pilobolus* appeared in John Ray's "Historia Plantarum" in 1688. However, mycological investigations of that period were primarily descriptive in nature, and many years elapsed before the diurnal reproduction of *Pilobolus* was fully described. Conceivably some of the early workers were cognizant of the periodicity, but it is impossible to determine the extent of their knowledge from the three or four line descriptions they gave.

Indeed it was not until 1851 that the phenomenon of periodic asexual reproduction was described in detail. In that year Cohn (1851) set forth the correct chronological sequence of all stages in the life cycle

¹ Received for publication December 12, 1941.

Contribution from the Laboratories of Cryptogamic Botany and the Farlow Herbarium, Harvard University, no. 204.

The writer wishes to express his deep appreciation of the stimulating guidance received from Dr. Wm. H. Weston throughout the course of this research. Sincere thanks for helpful criticism and advice are also extended to Dr. K. V. Thimann, Dr. E. S. Castle, and Dr. D. H. Linder.

of *P. oedipus* Mont. Cohn, however, restricted his investigations to morphology and chronology and, except to express his belief that each fruiting body passes through its entire development within twenty-four hours, made no reference to the effect of external factors on sporangiophore development.

Four years later Bail (1855), comparing the sporangiophores of *P. crystallinus* (Wiggers) Tode and *P. roridus* (Bolt.) Pers., stated that the sporangiophores varied in dimensions according to "different light and air conditions." Although Bail presented no experimental data, his observations may be regarded as the first to relate reproductive periodicity in *Pilobolus* to the environment.

It is Eugène Coemans (1861) to whom we are indebted for the discovery that light is the primary factor in regulation of the life cycle of *Pilobolus*. In his "Monographie du Genre *Pilobolus*" Coemans offered the following original observations: (1) cultures kept in continuous darkness lose their periodicity; (2) in continuous darkness the sporangiophores, delaying sporangium formation, become greatly attenuated; and (3) the time of sporangium projection is directly dependent upon light. It is a well earned tribute to Coemans' powers of observation and analysis that since his researches only one major contribution (that of Gräntz) has been made to the problem of periodicity of reproduction in *Pilobolus*. The investigations of Klein (1872), Brefeld (1881), Grove (1884, 1934), and Buller (1934) contributed little to advance understanding of the factors involved in rhythmic reproduction. Brefeld (1881) made a fairly detailed study of sporangiophore behavior in continuous darkness, but this work was no more than an extension of Coemans'.

The last paper of significance is that of Gräntz (1898). Gräntz's most important observation was that not only continuous darkness, but continuous light also, causes a cessation of reproductive periodicity. With this work, research on factors influencing periodicity subsided. Subsequent authors were content merely to state that asexual reproduction in *Pilobolus* is periodic through the agency of light.

MATERIALS AND METHODS.—Of the many papers dealing with the culture of *Pilobolus* less than half-a-dozen contain reports of successful culture of this fungus in nutrient agar. Gräntz (1898), Bersa (1929), Krafczyk (1931, 1935), Swartz (1934), and Buller (1934) obtained adequate growth of mycelium and formation of mature fruiting bodies on dung agar. For the present experimental work the writer has used a 1 per cent dung decoction agar, prepared from a commercial fertilizer ("Bovung," a product of the Walker-Gordon Laboratory, Plainsboro, New Jersey). This nutrient medium, buffered to pH 6.5 by the addition of $\text{Na}_2\text{HPO}_4 \cdot 12 \text{H}_2\text{O}$ and KH_2PO_4 , each to $\frac{1}{200}$ molar concentration, has been successfully employed for over five years in culturing eight species, and has given consistently excellent growth.

In the experiments designed to test the effect on *Pilobolus* of alternating light and darkness, cultures

were kept in a large Thelco Electric Incubator maintained at 20°C ., in order to obviate the factor of a diurnally fluctuating temperature. Four sixty-watt bulbs provided illumination, which was made of uniform intensity by passing it through a ground glass plate. An electric fan installed in the incubator provided an air circulation sufficiently rapid to prevent a change in temperature when the light went on or off. For reasons to be explained later, cultures subjected either to continuous light or to continuous darkness were kept at room temperature.

Since light exerts a formative or morphogenic influence on the developing fruiting bodies of *Pilobolus*, observation of cultures kept in continuous darkness had to be carried out in light passed through a monochromatic filter (Jena filter #RG 5) which cut out all rays shorter than 6,700 Å. Such light, barely adequate for observation, had no appreciable influence on the developing sporangiophores.

THE LIFE CYCLE OF PILOBOLUS.—For full understanding of the experiments to follow, knowledge of the behavior of *Pilobolus* in both agar and dung culture is necessary. In the latter type of culture the sporangiophores originate during the afternoon from hyphal swellings, or fruiting body primordia, which are either upon or just below the surface of the dung. In the early hours of the evening each sporangiophore enlarges at its apex to form a sporangium. Shortly after midnight the subsporangial swelling begins to appear. In the course of the remaining hours of darkness the fruiting body matures completely, as the spores are cut out and the sporangial wall becomes thickened and blackened. In late morning the sporangium dehiscens, and is soon projected with explosive violence from the sporangiophore, which simultaneously collapses. By mid-afternoon, as a new crop of sporangiophores begins to emerge from recently formed fruiting body primordia, all fruiting bodies have discharged their sporangia. It is important to remember that in dung cultures of *Pilobolus* all sporangiophores are in approximately the same stage of development at any hour of the day or night.

Interpretation of the life cycle of *Pilobolus* in agar culture is greatly facilitated by the fact that the mycelium is completely submerged within the (transparent) medium. This striking habit of growth makes it possible to study hyphal structure in great detail, and to follow the formation and development of fruiting body primordia under high dry magnification. The following description of a life cycle in agar is for *P. Kleimii* van Tieghem, but may be considered representative of the genus.

The fruiting body primordium, or trophocyst, so termed by Morini (1900), arises as the localized accumulation of coarsely granular, orange-red protoplasm. Receiving a continuous supply of protoplasm, the young trophocyst slowly swells (fig. 1a-c) and ultimately is isolated from the mycelium by the formation of two septa (fig. 1d). Under the influence of the still streaming protoplasm, which is now prevented by the septa from entering the trophocyst,

that portion of the hypha immediately contiguous to the proximal septum swells slightly, forming an apophysis (fig. 1e). During apophysis formation the trophocyst absorbs water, presumably through a change in permeability of the walls, and increases in diameter. Simultaneously the trophocyst protoplasm becomes increasingly vacuolate. A mature trophocyst (fig. 1f) is ovate-cylindrical in shape, with a thick peripheral layer of protoplasm and a single large central vacuole.

one-half hours later the subsporangial swelling (fig. 1j) is clearly indicated. The fruiting body is completely formed (fig. 1k) eleven to twelve hours after sporangiophore emergence from the agar. Subsequently the sporangium dehisces, and the fruiting body collapses.

It is evident that the periodicity of asexual reproduction exhibited by *Pilobolus* in nutrient agar is by no means so precise as that exhibited in dung. In the latter type of culture, at any hour of the day

Fig. 1. Schematic diagram of a section through an agar culture of *P. Kleinii*, showing development of trophocysts and sporangiophores; a-c, successive stages in formation of young trophocyst; d, septa isolating trophocyst from subtending hypha; e, apophysis; f, fully mature trophocyst with central vacuole; g, sporangiophore after emergence from agar; h, apical enlargement of sporangiophore to form sporangium; j, beginning of subsporangial swelling; k, mature fruiting body.

The findings of the writer do not corroborate the belief of past workers that trophocyst formation takes place only during the morning, within the comparatively short space of a few hours. On the contrary, trophocysts can be found in all stages of development at any time, and can require as much as forty-eight hours for development. Further development, however, does follow a fairly rigid time schedule. Between 3 P.M. and 5 P.M. a sporangiophore grows forth from the distal end of the trophocyst.

The sporangiophore, which may be considered an extension of the trophocyst since the protoplasm and central vacuole of both are continuous, exhibits marked negative geotropism and positive phototropism. Only after having grown out of the agar (fig. 1g) does the sporangiophore pass through the successive stages of development outlined for sporangiophore behavior in dung culture. The period during which sporangiophores emerge from the agar extends from approximately 3 P.M. to 10 P.M. Formation of the sporangium (fig. 1h) takes place about four to five hours after this emergence. Three and

or night all sporangiophores are in approximately the same stage of development. In agar culture, at any particular moment the sporangiophores can be as many as seven hours apart in their development. The explanation of this striking difference in behavior is to be found in the place of formation of the trophocyst in the two types of culture. In dung culture all trophocysts are formed upon or just below the surface of the dung. The sporangiophores which arise from the trophocysts protrude into the air almost simultaneously, and undergo subsequent developmental changes synchronously. In agar culture, however, trophocysts are formed at different levels within the substratum, and, although the sporangiophores grow forth from these trophocysts simultaneously, formation of sporangia, etc., cannot take place until the sporangiophores have emerged from the agar. Since sporangiophores may emerge from the agar during a period extending from 3 P.M. to 10 P.M., these sporangiophores, following their emergence, may be seven hours apart in development. The time of emergence from the agar of the sporangio-

phore is in part a function of the depth of the trophocyst within the agar. One may, therefore, conclude that in dung culture periodic maturation of fruiting bodies depends upon periodic emergence of the sporangiophore from the trophocyst, and in agar culture periodic maturation of fruiting bodies depends upon periodic emergence of the sporangiophore from the agar.

The writer has found it possible to grow agar cultures of *Pilobolus* in an atmosphere of pure nitrogen, in Kolle flasks. In these completely anaerobic agar cultures there is a striking parallel to the habit of growth in ordinary dung culture: the majority of trophocysts are formed on the surface of the substratum. A consideration of the place of trophocyst formation in the three types of culture (dung, aerobic agar, anaerobic agar) leads logically to the suggestion that *Pilobolus* is a microaerophilic organism. The soundness of this hypothesis is being tested experimentally.

EXPERIMENTS.—Determination of the presence or absence of periodicity in cultures subjected to a particular set of light conditions was most effectively made by a count of the number of sporangiophores in each of five arbitrarily chosen stages of development. Any significant deviation from the standard count, obtained from cultures subjected to normal twenty-four-hour alternation of light and darkness, could then be interpreted as altered sporangiophore behavior. The five stages of sporangiophore development chosen are shown in figure 2. Results of the following experiments are presented in tabular form, showing the number of sporangiophores in each stage at 8 A.M. and at 8 P.M. The number given represents the total for an indicated number of Petri plate cultures. Interpretation of the results has been further simplified by grouping together the percentages and totals of stages I and II (the period of emergence and elongation) as group A, stages IV and V (the period of maturation) as group C, keeping separate stage III (the period of sporangium formation) as group B. This procedure of grouping is justified by the fact that, in cultures which have been subjected to alternating light and darkness, each of the three periods represents an approximately equal length of time (four hours) in the development of the sporangiophore above the agar. Since the experiments were performed with different numbers of Petri plate cultures, and since these cultures varied in age, comparisons of the results of the experiments cannot be made on the basis of the absolute numbers of sporangiophores observed. To obviate this difficulty, the group counts have also been expressed as percentages. The following experiments were carried out with *P. microsporus* Klein.

Normal alternation of light and darkness; Experiment 1.—In order to establish the standard count, thirteen Petri plate cultures were subjected to light from 8 A. M. to 8 P. M., and to darkness from 8 P. M. to 8 A. M., over a period of five days. Counts made of the sporangiophores at 8 A. M. and 8 P. M. each day are given in table 1. Total counts and percentages for

the entire five days of groups A, B, and C were as follows: at 8 A. M.—group A, 1,997 (96.9 per cent); group B, 62 (3.0 per cent); group C, 3 (0.1 per cent); at 8 P. M.—group A, 47 (1.0 per cent); group B, 266 (5.9 per cent); group C, 4,189 (93.1 per cent). These figures were used as standards with

Fig. 2. Diagram showing five stages of *Pilobolus* sporangiophore development above the agar. These stages were arbitrarily chosen for use in determining presence or absence of periodicity of reproduction in *Pilobolus* cultures subjected to various conditions of illumination.

which to compare results obtained from other experiments.

The totals just given for the three groups are of great value in demonstrating the long interval of time during which sporangiophores may emerge from the agar. Thus the presence of 266 sporangiophores in group B at 8 P. M. indicates that sporangiophore emergence from the agar must have begun at least four hours earlier. Furthermore, the number (4,189) of sporangiophores in the period of maturation at the end of twelve hours of darkness is markedly greater than the total number of sporangiophores in all groups (2,062) at 8 P. M., showing that sporangiophores must have continued to emerge from the agar after 8 P. M. The presence of 62 sporangiophores in the period of sporangium formation at 8 A. M. may possibly indicate that sporangiophores which emerge from the agar late in the evening elongate for a longer time before forming sporangia than do sporangiophores which emerged from the agar during the afternoon or early evening. If this were not so,

the last sporangiophores to emerge from the agar (at 10 P.M.) would have formed sporangia by 2 A.M., four hours after emergence, and would be well into the maturation period by 8 A.M.

Reversed alternation of light and darkness; Experiment 2.—If periodicity of asexual reproduction is caused by daily alternation of light and dark periods, a reversal of periods should bring a reversal of periodicity—that is, the majority of sporangiophores should be in group C at 8 P.M., and the ma-

riod, no matter what successive twelve-hour intervals of the day or night the light and dark periods may cover.

Since in both the first and second experiments the cultures of *Pilobolus* were kept at constant temperature and, nevertheless, exhibited periodicity of reproduction, there is strong indication that temperature—the only other external factor which might effect rhythmic formation of fruiting bodies—does not play an important part in periodicity.

* Conditions of observation made it impossible to distinguish between stages IV and V.

jority in group A at 8 A.M. The data obtained from such an experiment, and presented in table 2, show that this condition actually obtained. Counts on nine plates for five days gave the following totals and percentages: at 8 A.M.—group A, 1,178 (96.3 per cent); group B, 45 (3.7 per cent); group C, 0 (0 per cent); at 8 P.M.—group A, 30 (2.4 per cent); group B, 19 (1.5 per cent); group C, 1,204 (96.1 per cent).

This single experiment gave definite indication that the periodicity exhibited by *Pilobolus* is not inherent, for it followed that sporangiophores can be caused to mature at any time of the day or night, simply by suitably adjusting the alternating periods of (artificial) light and darkness. If an agar culture of *Pilobolus* is exposed to alternating twelve-hour periods of light and darkness, a majority of fruiting bodies invariably will be found mature at the end of the dark period, immature at the end of the light pe-

Continuous darkness; Experiment 3.—The contention of Coemans (1861), Brefeld (1881), and others, that cultures of *Pilobolus* do not show periodicity when kept in continuous darkness, was corroborated by the results of the third experiment, in which counts were made for four days on thirteen plates subjected to continuous darkness. The results are shown in table 3. These results have not been totaled, since this treatment would detract significance from several important points. These points are: (1) the number of sporangiophores in group A, the period of emergence and elongation, shows a steady increase over the four days; (2) sporangiophores in group B, the period of sporangium formation, do not begin to appear in significant numbers until at least forty-eight hours have elapsed following emergence from the agar; and (3) a minimum of three or more days is required for the entire process

of sporangiophore development. Of particular importance is the fact that approximately equal numbers of sporangiophores are to be found in stage I at each observation time.

Continuous light; Experiment 4.—Since continuous darkness had been shown to prevent periodicity, continuous illumination was then employed. Counts made on twenty-four cultures grown for five days in continuous light (see table 4) yielded the following totals and percentages: at 8 A.M.—group A, 1,171 (26.9 per cent); group B, 1,424 (32.7 per cent); group C, 1,758 (40.4 per cent); at 8 P.M.—group A, 989 (27.7 per cent); group B, 1,104 (30.9 per cent); group C, 1,477 (41.4 per cent). These results show that at any time of the day or night significant numbers of sporangiophores can be found in all three periods of development. The only point of agreement between the results of the experiments with continuous light and continuous darkness is that, in both, counts for stage I indicate that sporangiophores emerge from the agar irrespective of the time of day or night. In continuous darkness the sporangiophore continues to elongate for many hours before forming a sporangium; in continuous light sporangium formation takes place within a very short time after the sporangiophore has emerged from the agar—a fact which can be determined also from measurement of the average length of mature fruiting bodies.

The last two experiments (conducted at room temperature) gave further evidence of the unimportance of temperature for the periodic formation of mature fruiting bodies. Room temperature was allowed to fluctuate between 20°C. during the day and 13°C. during the night. This daily fluctuation had no observable effect on the cultures. At each observation time sporangiophore counts indicated continuing lack of periodicity.

Alternating light and darkness followed by continuous light; Experiment 5.—With alternating periods of light and darkness firmly established as the cause of periodicity of reproduction, the next step was to determine how long a period of continuous illumination was necessary to cause cultures which had been subjected to alternating light and darkness to lose their periodicity. The nine *Pilobolus* cultures of the second experiment were used for this purpose. At the end of the last period of illumination, when the cultures showed the usual high percentage of sporangiophores in group A (the period of emergence and elongation), the light was allowed to remain on for forty-eight more hours. The results of observations made at succeeding twelve-hour intervals during the extra two days of illumination appear in table 5, together with the counts which had been made during the preceding twenty-four hours. Periodicity disappeared within twelve hours, as shown by the percentages obtained at 8 P.M., at the end of the first twelve hours of extra illumination: group A, 23.5 per cent; group B, 37.6 per cent; group C, 38.9 per cent. This distribution is characteristic of cultures growing in continuous light.

The extremely short interval of time sufficient to cause loss of periodicity under these conditions depends upon the fact that the sporangiophores continue to emerge from the agar when the illumination is extended, rather than ceasing to emerge at the end of the usual seven-hour interval.

Continuous light followed by alternating light and darkness; Experiment 6.—The results obtained by reversing the conditions of the preceding experiment are given in table 6. Here eight plates which had been growing in continuous light were subjected at 8 A.M. to twelve hours of darkness, followed by twelve hours of light, and so on. Again, twelve hours were sufficient to establish a sporangiophore count characteristic of cultures exposed to alternating light and darkness. Thus at 8 P.M. the percentages were as follows: group A, 4.1 per cent; group B, 1.4 per cent; group C, 94.5 per cent. This percentage distribution obtained because the sporangiophores had ceased to emerge from the agar at 10 A.M. (the usual two hours after illumination had stopped).

Continuous darkness followed by alternating light and darkness; Experiment 7.—Somewhat the same phenomenon was observed when continuous darkness was used in place of continuous light. Although experiments were not carried out on a statistical basis, it is possible to state that cultures which have been kept in continuous darkness and then exposed to alternating light and darkness, do not exhibit periodicity until after twenty-four hours have elapsed. The reason twenty-four hours are required under these conditions, rather than the twelve hours of the preceding two experiments with continuous light, is clear on analysis. At the end of a period of continuous darkness most of the sporangiophores are in stage II. When the culture is illuminated at (for example) 8 A.M., the sporangiophores which are in stage II begin to form sporangia, but also more sporangiophores continue to emerge from the agar. Thus at the end of twelve hours of light, sporangiophores are to be found in all stages of development, although most are in the maturation period. After the light has been discontinued at 8 P.M. the sporangiophores continue to emerge, but only until 10 P.M. As a result, at 8 A.M. the next morning (twenty-four hours following the first twelve-hour exposure to light) the sporangiophore count is similar to that of cultures which have been exposed to normal alternating light and dark periods.

No attempts have been made to determine what length of exposure to continuous darkness is sufficient to cause cultures growing in alternating light and darkness to lose their periodicity.

The observations and experiments just presented have given complete confirmation to the general belief that it is alternation of day and night which brings about daily formation and maturation of the fruiting bodies of *Pilobolus*. The experiments have demonstrated that periodicity of reproduction is not the expression of a behavior pattern fundamentally independent of the environment, but rather a characteristic reaction to a particular set of environmen-

tal stimuli. The problem thus becomes one of discovering how *Pilobolus* reacts as it does. What further advance the writer has been able to make has come from an analysis of the preceding seven experiments in terms of sporangiophore behavior within the agar.

OBSERVATIONS ON SPORANGIOPHORE BEHAVIOR WITHIN THE AGAR.—It will be recalled that in agar cultures of *Pilobolus* exposed to alternating light and darkness, the diurnal succession of crops of mature fruiting bodies was found to depend upon sporangiophore emergence from the agar during a definitely limited interval of time only. Cultures exposed to

the dark period began, and resumed growth seven or eight hours after the (following) light period had started. Sporangiophores growing within the agar in cultures exposed to continuous light or continuous darkness, on the other hand, did not exhibit this daily cessation and resumption of growth, but elongated through the agar at a steady rate, without forming any swellings.

These observations on sporangiophore behavior within the agar fully explain the time of sporangiophore emergence from the agar. In cultures exposed to normal alternating light and darkness sporangio-

Fig. 3-7. Diagrams of different behavior patterns of sporangiophores growing within the agar, in *Pilobolus* cultures subjected to alternating twelve-hour periods of light and darkness.—Fig. 3. *P. simplex*.—Fig. 4. *P. microsporus*.—Fig. 5. *P. longipes*.—Fig. 6. *P. proliferans*.—Fig. 7. *P. ramosus*. In all figures, a-d represent the termination of the first, second, third, and fourth day's growth of the sporangiophore respectively.

continuous light or continuous darkness did not exhibit periodicity because the sporangiophores did not emerge from the agar rhythmically. The explanation of the phenomenon of periodic emergence from the agar was finally obtained from analysis of certain peculiar swellings regularly exhibited by sporangiophores of *P. microsporus* (fig. 4) when allowed to elongate through the agar for several days. Preliminary observation of sporangiophore growth under such conditions showed that the sporangiophore did not elongate through the agar continuously, but stopped growth during the evening. Next morning the sporangiophore swelled laterally at its apex (fig. 4a), and resumed forward growth in the afternoon. This behavior was repeated daily until the content of the trophocyst had become exhausted, or the sporangiophore had emerged from the agar. Since each swelling represented the termination of one day's growth, a count of the number of swellings (fig. 4a-d) gave the age, in days, of the sporangiophore.

When these observations were extended to cultures exposed to twelve-hour alternating periods of light and darkness, it was found that the sporangiophores stopped elongating about two hours after

phores emerge from the agar between 3 P.M. and 10 P.M., since the sporangiophores within the agar are elongating during that interval of time only. In cultures exposed to continuous light or continuous darkness sporangiophores emerge from the agar continuously because the sporangiophores within the agar elongate continuously.

Investigations of sporangiophore behavior among other species of *Pilobolus* have yielded interesting results. In all species examined, cultures exposed to alternating light and darkness showed daily cessation and resumption of growth of the sporangiophore within the agar. However, the manner in which this phenomenon is expressed varies among the species. An extreme divergence from the growth pattern of *P. microsporus* is seen in the sporangiophore behavior of *P. proliferans* sp. nov.² (fig. 6). In this spe-

² Since the writer's paper on the taxonomy of *Pilobolus* will not appear for several months, brief diagnoses (based on growth in nutrient agar culture) of three new species of this genus are appended here.

P. proliferans sp. nov. (fig. 6). Sporangiis lenticularibus v. ovoideis; columellis conicis; vesiculis subsporangialibus subellipsoideis; sporangiophoris intra substratum ex trophocystibus cotidie renovatis; trophocystibus ovato-cylind-

cies the sporangiophore which stops growing at 10 P.M. does not resume growth in the afternoon of the next day. Instead, the protoplasm withdraws completely from the sporangiophore, flows back into the trophocyst, and a septum is laid down at the base of the sporangiophore. Then at 3 P.M. a new sporangiophore is protruded from the trophocyst. If in turn this sporangiophore does not emerge from the agar by 10 P.M., the cycle is repeated. Trophocysts of this species have been seen with ten sporangiophores, representing as many days' growth.

A growth pattern which is intermediate between that of *P. microsporus* and *P. proliferens* is displayed by the sporangiophore of *P. longipes* van Tieghem (fig. 5). In this species the protoplasm withdraws only halfway down the sporangiophore, after the latter has stopped elongating. A transverse wall is laid down at this point, and at 3 P.M. the next day a new sporangiophore grows forth from the old, just proximal to the transverse septum. A modification of this type of sporangiophore growth pattern is found in *P. ramosus* sp. nov. (fig. 7) and also in *P. Kleinii* and *P. crystallinus*. In all three species the protoplasm withdraws a varying distance down the sporangiophore.

The sporangiophore of *P. simplex* sp. nov. (fig. 3) behaves almost precisely as that of *P. microsporus*: there is no retraction of protoplasm, no branching of the sporangiophore. However, in *P. simplex* no lateral swelling takes place after elongation for the day has ceased. Thus this growth pattern lacks any regularly recurring morphological peculiarity, and except by daily observation we are unable to determine how long a sporangiophore has been growing within the agar.

Among those species which possess branching sporangiophores a further significant phenomenon has been observed. After growth of the sporangiophore has ceased at 10 P.M., occasionally not all of the protoplasm withdraws toward the proximal end. The protoplasm which remains behind becomes walled off from the rest of the sporangiophore. In the afternoon of the following day a slender sporangiophore, much smaller in diameter than normal, grows forth from the walled-off remnant of protoplasm at the same time (3 P.M. to 5 P.M.) that the new sporangiophore is normally growing forth from the old. The slender "secondary" sporangiophore behaves precisely as the primary sporangiophore, branching characteristically with each day's growth.

Mention should be made of another phenomenon of possible significance for the problem of periodicity. In cultures of *P. Kleinii* exposed to alternating light and darkness, those sporangiophores which chance to emerge from the agar after 10 P.M. continue to grow for only a short while. After cessation of growth does take place, the protoplasm withdraws, and further activity is deferred as usual until the afternoon of the next day, when the new sporangiophore grows forth from the old. Maturation of the sporangiophore thus depends upon emergence of the sporangiophore from the agar before 10 P.M. The writer believes that in tables 1 and 2 the sporangiophores in group A, after the period of darkness, may be those sporangiophores which emerged from the agar after 10 P.M., and thus should not have been counted. (At the time the first and second experiments were conducted, this phenomenon had not yet been discovered.)

Occasional references to branching sporangiophores have appeared in the literature of *Pilobolus*. Léveillé (1826) described a species of *Pilobolus* possessing trophocysts which gave rise to three or more sporangiophores. Coemans (1861), Klein (1872), Grove (1884, 1934), and Zopf (1888) all noted the (infrequent) occurrence of branched sporangiophores in dung culture. Morini (1906) described as a new species, *P. Borzianus*, a form in which the trophocyst regularly protruded two to three sporangiophores. Of all these authors, Coemans alone attempted to relate such "abnormal" branched sporangiophores to an environmental influence. He had observed that all the sporangiophores of a dung culture of *Pilobolus* ceased to grow following the occasion of a violent storm, but on the following day branched to give rise to new sporangiophores. The sporangiophores undoubtedly stopped growth because of early darkness brought about by the storm. Although these workers regarded branching sporangiophores as abnormal, it would be more nearly correct to call such sporangiophores atypical.

DISCUSSION.—The investigations presented in this paper have resulted in clarification of the problem of periodicity of asexual reproduction in *Pilobolus*. The most important result has been definitive establishment of the fact that periodic reproduction is the result of reaction to the influence of a single external factor—light. Further analysis of this periodicity has shown that in cultures exposed to alternating light and darkness periodic production of mature fruiting bodies is the inevitable consequence of periodic emergence of the sporangiophore (periodic emergence from the trophocyst, in dung culture; periodic emergence from the agar, in agar culture).

To be sure, the fact that sporangiophores regularly emerge from the trophocyst only during the afternoon, has been pointed out by previous workers. However, these investigators apparently regarded periodic sporangiophore emergence from the trophocyst as but one of several periodic steps in the development of the fruiting body, rather than as the one

step responsible for periodicity. This misunderstanding of the true significance of sporangiophore emergence was a logical result of the then prevalent belief that trophocysts are produced periodically, and that periodicity accordingly originates with trophocyst formation. This may perhaps explain why even so careful a worker as Gräntz failed to notice that in cultures of *Pilobolus* subjected either to continuous light or to continuous darkness, the sporangiophores do not grow forth from the trophocyst periodically. However, it should be pointed out, in extenuation, that in their experiments with various conditions of illumination, Gräntz and others were concerned not with the possible effect on the time of sporangiophore emergence from the trophocyst, but with the effect on subsequent development.

Now that periodic emergence of the sporangiophore has been shown to be the *sine qua non* of periodic formation of mature fruiting bodies, experimental investigation of the problem of periodicity in *Pilobolus* can be confined to the phenomenon of periodic sporangiophore emergence. For such investigations agar culture of *Pilobolus* is greatly advantageous, since the phenomenon is repeated daily by each sporangiophore within the agar. Perhaps a more nearly complete understanding of periodicity in *Pilobolus* may result in some clarification of the mechanisms involved in similar biological rhythms.

SUMMARY

In nutrient agar, as on dung, *Pilobolus* exhibits a diurnally rhythmic asexual reproduction. The periodicity in the former type of culture is not so precise as in the latter.

The results of experiments in which agar cultures of *Pilobolus* were subjected to various conditions of illumination demonstrate that the reproductive pe-

riodicity of this fungus is not inherent (autonomic) but completely conditioned by the diurnal alternation of day and night. Maturation of sporangiophores, which normally takes place during the morning, can be made to occur at any hour of the day or night, by suitably adjusting the alternating twelve-hour periods of light and darkness. The periodicity can be made to disappear by subjecting cultures either to continuous light or to continuous darkness.

In agar cultures the sporangiophores arise from fruiting body primordia, or trophocysts, which are completely submerged within the substratum, unlike the condition in dung where trophocysts are formed just below or upon the surface of the substratum. In agar cultures subjected to alternating periods of light and darkness the sporangiophores which arise from the trophocysts exhibit a daily cessation and resumption of growth, so long as they remain within the agar. Only after emergence from the agar can the sporangiophores develop into mature fruiting bodies. Consequently, periodic production of mature fruiting bodies in *Pilobolus* is considered to be dependent upon periodic emergence of the sporangiophores: periodic emergence from the agar, in agar culture; periodic emergence from the trophocyst, in dung culture.

The results of certain experiments suggest that *Pilobolus* may be a microaerophilic organism.

Sporangiophores within the agar which exhibit daily cessation and resumption of growth, form definite growth patterns characteristic for each species.

Brief descriptions are given of three new species: *P. ramosus* sp. nov.; *P. proliferens* sp. nov.; and *P. simplex* sp. nov.

PHOTOSYNTHESIS AND ABSORPTION IN BLUE RADIATION ¹

G. Richard Burns

IN EARLIER work with white pine seedlings (Burns, 1937, 1938), a purely arbitrary value called the primary absorption spectrum was determined for each of the various types of plants. The primary absorption spectrum was the incident radiation minus the reflected, minus the amount transmitted by an acetone solution of the pigments at about the same concentration as in the plant. The spectra of the reflection, of the transmission, and of the sources were made with wide slits. Granted a constant quantum yield at the wave lengths involved and assuming that only radiation thus primarily absorbed was photosynthetically effective, the relative amounts of photosynthesis in the various portions of the spectrum were calculated and found to agree, within a few per cent, with the experimentally determined values at wave lengths greater than 5,000 Å. To the extent of this rather surprising agreement, it was assumed that the primary absorption spectrum and the curve for photosynthesis at equal incident quanta intensity against wave length were the same within certain limits. However, between 4,000 Å and 5,000 Å, the amount of photosynthesis was found to be about one-half of that indicated by the primary absorption spectrum. In contrast to this low photosynthesis in pine, Hoover (1937, fig. 1) found a maximum in wheat within this region. The results of other investigators vary and will not be included, since Gabrielsen (1940) has given a general review of this work.

The main purpose of the experiments in this paper is to show that this difference in the behavior of pine and wheat in the blue region is due to differences in the two plants and not to errors or differences in the experimental methods. Since the same apparatus was also suitable for the partial investigation of several other problems, the results of these incomplete investigations, while not so conclusive, are also included.

In the study of photosynthesis, curves giving the amounts of photosynthesis at equal incident quanta intensity against wave length are of value only in so far as they yield information on photosynthesis at equal absorbed quanta. The approximate agreement of the curves (fig. 1) for wheat and pine at wave lengths longer than 5,000 Å, in spite of the obvious differences in color and absorption, shows that the corresponding curves on an absorbed quanta basis would differ. While accurate determinations of the fraction of incident radiation absorbed by a land plant under the conditions of these experiments is beyond our ability, such determinations as we have been able to make indicate that the amounts of photosynthesis in pine seedlings at 4,358 Å, 5,461 Å, and 5,780 Å are less than would be called for by the absorbed quanta when compared to other wave lengths. The divergence is greatest at 4,358 Å. In wheat this difference between the amount of photosynthesis and

absorption is not great enough to exceed the experimental errors of the determinations. It would appear that pine has more photosynthetically inactive absorption at these three wave lengths than wheat.

The primary absorption spectra of various wheat plants were also determined, and the results indicate that, in this plant, there is no agreement between the primary absorption spectra and the amount of photosynthesis.

Fig. 1. H—Hoover's results with wheat graphed as photosynthesis at equal incident quanta intensity with maximum photosynthesis set at 90. BP—Curve for pine grown in blue light. The portion in dashes was covered in one experiment and indicates the average for these wave lengths. RP—Curve for pine grown in red light. The vertical dashes show the wave lengths studied in the present work.

APPARATUS AND METHOD.—The top of the plant was enclosed in a double walled, cylindrical glass container, 25 mm. in internal diameter and 120 mm. high, with distilled water from a bath at 27.0° circulating between walls. Large, polished Corning monochromatic filters were placed on either side of the container, at a distance of 20 mm., followed by 30 mm. water filters, and, finally, banks of four mercury lamps (type H 1, 400 watts). The plant was thus illuminated from two opposite sides by sources of considerable area. The light intensity was varied by turning off the middle two lamps in each bank and by moving the lamps. This last is an undesirable feature of the method, since moving the lights away from the plant decreases the angle at which light falls on the plant and makes more light, as measured by a flat surface thermopile, necessary to produce the same amount of photosynthesis. The error thus introduced was determined experimentally and found to be less than five per cent in extreme cases. The values given are corrected for this effect. The Corning filters transmitted less than one per cent of stray radiation in wave lengths that cause photosynthesis.

¹ Received for publication November 26, 1941.

Published with the consent of the Director of the Vermont Agricultural Experiment Station.

Changes in the carbon dioxide concentration were determined by passing the air through 4 or 5 cc. of conductivity water surrounding a glass electrode and measuring the resulting voltage with a vacuum tube potentiometer. Since the experiment was designed to determine the light intensity at which photosynthesis balanced respiration, the sign of the change of carbon dioxide concentration and not its amount was determined. In order to obtain sufficient sensitivity with the glass electrode a carbon dioxide concentration of about 0.06 per cent was used, but with the rapid movement of air and the low light intensity this should not affect the results. With the amount of plant material employed, a 1 per cent increase in light intensity above the compensation point could be detected in five minutes. This system of determining changes in carbon dioxide concentration has the advantage of not withdrawing a sample of the gas, but it is very sensitive to temperature and pressure changes and to impurities in the water. The glass electrode system, the bellows air pump, and the water supply for the plant chamber were in an oil bath at $27.0 \pm .01^\circ$. The air was cooled between the glass electrode and pump to lower the humidity before returning it to the plant chamber.

In carrying out a determination, one or two days before the experiment the tops of the plants were sealed in the chamber by very soft grafting wax and illuminated with water-filtered radiation from an incandescent lamp for eighteen hours a day. The mercury lamps with one of the monochromatic filters were used to illuminate the plant for two or three hours before the actual determinations were begun. Readings of the carbon dioxide concentration were taken every five minutes, and the light intensity was changed by 10 per cent steps until the intensity was reached which kept the carbon dioxide concentration most nearly constant for four periods of five minutes each. The purpose of the four readings was to see whether or not the compensation point was shifting. Four readings were then made at a light intensity on the other side of the compensation point and the intensity at compensation determined by interpolation to the nearest five per cent. The light intensities were measured by a photronic cell. The filters were then changed, the plant illuminated for an hour in the new radiation, and the compensation point in this radiation determined. The last determination of the day was usually in the same radiation as the first, as a check against change in respiration or photosynthesis. After the plant had been removed, the light intensities were checked by a thermopile with a 25 mm. water cell. The results should be accurate to five per cent, since with this amount of preliminary lighting, the increase in efficiency, while usually noticeable, is much slowed down.

EXPERIMENTAL DATA AND DISCUSSION.—We have always found respiration to be practically constant over a period of eight hours if the plant has not been injured during installation in the reaction chamber. In some cases in which the compensation point was changing too rapidly to be measured, we have found

respiration to be changing only slightly. However, since Emerson (unpublished work) has found marked effects on respiration after illumination with certain wave lengths in the blue, measurements were made after illumination at 4,358 Å, but no changes greater than 2 per cent were found, which was the limit of accuracy of the glass electrode for this type of measurement.

The wheat plants used in this work were grown in a prepared soil that had been found to give a particularly lush growth and a much wider leaf than ordinary soil. The conditions of growth and the number and arrangement of the leaves were varied to make the primary absorption differ. Table 2 gives reflection and transmission values which are not absolute but are specific for the instrument with which they were made. The transmission value is particularly poor in cases in which more than one layer of leaves is involved, due to the difficulty of duplicating the register of the leaves, and does not adequately take into account variations in diffusion. A description of the plants used in this work follows:

1. Marquis wheat grown in artificial light, about fourteen days old. Single layer of leaves held flat toward light by wire frame and fine thread.
2. Wheat, artificial light, leaves random and same number as above.
3. Wheat, artificial light, triple layer of leaves held flat; before the second determination, the leaves, which were held too firmly at the top, had buckled out and filled the chamber. Slightly bleached at end of runs.
5. Wheat, artificial light, leaves random and same number as 3. Slightly bleached at end of runs.
6. Wheat grown in shade in greenhouse. Same size as above but about one month old. Single layer of leaves held flat.
7. Wheat, greenhouse, single layer held flat.
8. Wheat, greenhouse, triple layer held flat.
9. Wheat, greenhouse, triple layer held flat.
10. Wheat, grown under blue glass filter. Double layer of leaves held flat. Slightly bleached at end of runs.
11. Wheat, blue filter, mostly double layer but with some single layer.
12. Wheat, artificial light, single layer held flat.
20. White pine, grown in shade in greenhouse, new growth only.
21. White pine, greenhouse, new growth.
22. White pine, greenhouse, new growth.
23. White pine, greenhouse, lighter color, new growth.
30. Norway spruce grown under red glass filter.
31. Norway spruce grown under blue glass filter.
32. Norway spruce grown under blue glass filter.

In the tables and figures, Y is used to designate the 5,780 Å line; G, the 5,461; B, the 4,358; V, the 4,048; and UV, the 3,650. The light intensities are in arbitrary units based on incident calories. The efficiencies are based on incident quanta with the efficiency of the blue arbitrarily set at 90 for wheat and the green set at 50 for pine and spruce.

Photosynthesis in blue light.—Figure 2 and table 1 give the incident intensities of the different radiations that were necessary to keep the carbon dioxide constant. Figure 2 shows clearly that wheat is able to

TABLE 1. *The incident intensities of the yellow, green and blue mercury lines required to keep the carbon dioxide concentration constant with various plants. The relative efficiency is the photosynthesis at equal incident quanta intensity with the value for one wave length set at an arbitrary figure and the assumption of a constant quantum yield.*

use incident blue light more efficiently than pine or spruce. It should be remembered that no attempt was made to determine these values to better than five

per cent. The actual intensities were used in this diagram, rather than the customary relative intensities, so that plants with the same photosynthetic be-

havior but with different amounts of respiration are separated and do not fall on the same points.

The variation between the results with the same plant on successive days is very noticeable and is probably due to three factors: a change in the register of the leaves, due to over-night growth, in the case of plants that had more than one layer of leaves held in a frame; an over-night change in respiration; and another unknown factor, more clearly shown in

Fig. 2. Wave length and intensity of incident radiation required to keep the carbon dioxide concentration constant in the case of wheat, pine, and spruce. The scale of intensity for pine and spruce is two-thirds that for wheat. The purpose of the figure is to show that there is a difference in the behavior of pine and wheat in the blue.

earlier work in which photosynthesis was much higher than respiration, which sometimes causes a sudden increase in the amount of photosynthesis. Changing register of the leaves should affect the efficiency in blue radiation less than in the yellow or green, since blue radiation is more readily absorbed. This effect is best shown in plant 3, in which a triple layer of leaves was held flat the first day but buckled and filled the cylindrical container the second. Plants with a single layer of leaves (numbered 1, 6, and 7) and the plants with leaves distributed at random (numbered 2 and 5) should and do give more consistent results than plants with multiple layers of leaves (numbered 3, 8, 9, 10, and 11). The difference in the results with plant 8 may be due to a change in respiration.

Absorption and photosynthesis.—The absorption measurements (fig. 4) were made with a 175 mm. integrating sphere. A 10 by 20 mm. sample of the plant

was placed in the center and illuminated through a small opening in the front of the sphere. The phototube was placed inside the sphere facing the left side and 20 mm. from the center. Since the sphere was so small, it was tested by placing a flat magnesium oxide surface in the center and reflecting the radiation toward different portions of the interior. Reflection toward the entrance slit gave a reading of 100; to the right of the slit 96; left, 100; toward the right or left side, 99; toward the right rear, 103; left rear, 101. Reflection toward the left side threw most of the radiation on the shield which covered the back of the phototube. The inside of the sphere was coated with magnesium oxide from burning magnesium. The absorption measurements were not made on the

Fig. 3. Wave length and relative efficiency based on incident quanta for wheat with different pigment concentrations or different numbers of leaves in the reaction chamber. The efficiency of the blue radiation has been set at 90 in each case.

plants used in the experiments but on samples from similar plants. Since an appreciable amount of light passed between the needles in the measurements with pine, a correction was made for this by assuming

that all the blue radiation which was not reflected was absorbed and that the transmission in this case, 3.3 per cent of the radiation reflected by the magnesium oxide surface, was entirely due to radiation coming through cracks between the needles. Due to the different effects of line voltage variations on vapor and incandescent lamps, the measurements were made to 2 per cent.

The simplest concept of photosynthesis at different wave lengths would be to assume a constant quantum yield at all wave lengths capable of causing photosynthesis and to expect the amounts of photosynthesis to be proportional to the absorbed quanta. A comparison of the absorption values for wheat with the relative efficiency of the incident radiation (fig. 4 together with the additional efficiency values given in fig. 3) shows that this concept will apply to wheat, at the wave lengths studied, within the rather large experimental errors of the determination of these two values. In making this comparison it should be remembered that the efficiency of 90 in the blue is an assumption made necessary by the failure to find any suitable line source in the region of maximum absorption in the red. In view of Hoover's results, this assumption does not seem unreasonable. A group of lines around 7,000 Å may be isolated from the mercury lamps; these were tried in ten experiments with wheat and spruce, but the efficiency was about the same as in the yellow. Comparison of the absorption values for pine with the relative efficiency (fig. 4 and plants 20 to 24 in table 1) indicates that this simple concept does not hold for pine at any of these wave lengths. Apparently photosynthesis is far below absorption in the blue and well below it in the green and yellow. The efficiency of 50 for the green is assumed from previous work, and, if its validity is questioned, no definite conclusions can be drawn about photosynthesis in the green and yellow. Photosynthesis in the blue is so low, however, that there can be little doubt that it falls below absorption. Arithmetical comparison of photosynthesis and absorption would require absorption data from the actual plant used in the photosynthesis determination. These more accurate data would doubtless disclose differences between the absorption and photosynthesis in wheat, differences too small to be found by the present method.

Several things might be mentioned in regard to the individual efficiencies in figure 3. Only the figures for the second day are used, and with the plants numbered 7, 9, and 11 these differ widely from those on the first day. The results fall into three classes. The plants (numbered 8, 9, 10, and 11) with multiple layers of leaves and high pigment content had high relative efficiencies in the green and yellow. The plants with single layers of leaves and low pigment content (numbered 1, 2, and 3) had very low efficiency in the green and, from our point of view, too high efficiency in the yellow. The other plants (numbered 5, 6, and 7) with multiple layers of leaves of low pigment content or single layers of leaves of high pigment content fell between the other two

classes in the green and were lowest in the yellow. A fourth class would be Hoover's wheat with equal and lower efficiency in both the yellow and green. While none of these plants give the same results as Hoover's, there is enough variation between them to

Fig. 4. A is the absorption and E is the efficiency based on incident quanta. 1 = Single layer of wheat grown in artificial light. 7 = Single layer of wheat grown in shade. 10 = Double layer of wheat grown in shade. 21 = Pine grown in shade. Absorption and efficiency correspond within the experimental error with wheat, but with pine the large divergence increases toward the shorter wave lengths. The absorption and efficiency were measured on similar, but not the same plants.

lead to the supposition that Hoover's results could have been duplicated had the plants been grown in the same manner. These results emphasize the point, perhaps not too apparent to those not engaged in this type of work, that any photosynthesis curve applies accurately only to plants grown under identical conditions.

Primary absorption.—The agreement between the primary absorption spectrum of pine and the

amounts of photosynthesis in the region between 5,200 Å and 6,700 Å would be impossible if photosynthesis paralleled absorption. The results in the green and yellow, while not conclusive, are closer to the primary absorption spectrum than to the absorption spectrum of the plant. On the other hand, photosynthesis in wheat has much higher values in the green and yellow than the primary absorption spectrum demands. The primary absorption and the factor by which it must be multiplied to give the amount of photosynthesis are given in table 2. Since the factor varies from 1 to 3 and the factor for the green is always larger than for the yellow, there is no agreement between the primary absorption spectrum and photosynthesis with wheat. The agreement with pine could be explained on the basis of absorption in the yellow and green by photosynthetically inactive pigment.

Violet and ultra-violet radiation.—Table 3 gives a few determinations in the violet and ultra-violet region of the spectrum. Since the radiation was not strong enough to have photosynthesis balance respiration, the experimental technique was changed. After the plant had been in darkness for about fifteen minutes, the voltage of the glass electrode was determined at the beginning and end of a further period of about fifteen minutes' duration. The carbon dioxide concentration was then returned to a low value, the plant was illuminated, and the increase in time for the voltage to pass between the two values was determined. This gave a preliminary lighting time of fifteen or more minutes, which was too short for accurate work. The violet radiation was very weak, and the glass electrode was in an air bath, so that the probable error in the efficiency with pine would be plus or minus 75, and with wheat somewhat less. The error for ultra-violet, with its higher

TABLE 3. *The relative efficiency for pine and wheat at the blue, violet and ultra-violet mercury lines.*

Plant	Wave length	Incident intensity	Increase in time	Calc. intensity	Relative efficiency

intensity, would be around twenty for pine and ten for wheat. It can readily be seen that pine has little, if any, photosynthesis in the violet at 4,047 Å and none in the ultra-violet at 3,650 Å. Wheat, on the other hand, shows considerable photosynthesis at both these lines. The total pigments in the plants, diluted to one-fifth the usual strength in 90 per cent methyl alcohol, gave the following transmissions: pine, B—37 per cent, V—54 per cent, UV—47 per cent; wheat, B—44 per cent, V—64 per cent, UV—68 per cent. After the chlorophylls and some other pigments had been removed by shaking with alcoholic potassium hydroxide, the remaining yellow pigments in methyl alcohol solutions had the following transmissions: pine, B—88 per cent, V—89 per cent, UV—88 per cent; wheat, B—91 per cent, V—92 per cent, UV—96 per cent.

SUMMARY

The relative photosynthetic efficiencies, based on incident quanta, of white pine, Norway spruce and Marquis wheat have been determined in monochromatic radiation at several wave lengths, and some rough measurements of the absorption and the primary absorption have been made at the same wave lengths. The relative efficiency of both pine and spruce at 5,461 Å and 5,780 Å is the same as in our previous work, and the efficiency at 4,358 Å is about the same as 5,461 Å. The efficiency of wheat is highest in the blue, lower in the yellow, and the same or still lower in the green. The actual values depend

upon the concentration of the pigments or the number of leaves in a given volume. At 3,650 Å wheat shows large amounts of photosynthesis and pine none. The efficiency of wheat in the blue, green, and yellow radiation is roughly the same as its absorption and is not the same as its primary absorption. The efficiency of pine in the green and yellow radiation is much closer to the primary absorption than to the actual absorption, and in the blue radiation the efficiency is much lower than absorption. It would appear that pine has absorption of radiation by inactive pigments in the blue and probably in the green and yellow.

THE GROWTH AND METABOLISM OF OAT SEEDLINGS AFTER SEED EXPOSURE TO OXYGEN¹

Harry G. Albaum, John Donnelly and Seymour Korkes

IN THE course of experiments on the growth of oat coleoptiles after seed exposure to different oxygen concentrations, Albaum (1940) found that, after exposure to pure oxygen for periods of time ranging from about eight to twenty-four hours, seed subsequently grown in air failed to show any appreciable coleoptile growth as compared to the controls treated in a similar way with air. Oxygen consumption measurements on intact grains just after treatment, furthermore, showed that the rate of respiration was only 17 to 19 per cent lower in the oxygenated grains as compared to the aerated ones, while growth, as determined by measurements on final coleoptile length, was inhibited to the extent of 85 per cent.

Most of the experiments reported in the recent literature, with few exceptions, present the effects of oxygen treatment at tensions above atmospheric, and few of these treat of the effects on growth. Burk (1930) found that the respiration and growth of *Azotobacter* were inhibited when the organisms were grown in oxygen at atmospheric pressure. More recently, Bean (1941) reported that when *Pneumococcus*, Type I, was exposed to oxygen for twenty-four hours at a pressure of 900 mm. Hg., growth was completely inhibited. In the experiments described in the first paragraph, the oxygenation of the grains was done in water and at atmospheric pressure.

Several studies appear in the literature on the effect of oxygen on enzyme activity. Libbrecht and Massart (1937) found that oxygen under 5 atmospheres pressure completely inhibited the action of a succino-dehydrogenase preparation. The same kind of action was reported by Bohr and Bean (1940), who found that when oxygen at high barometric pressure (7.6 atm.) was bubbled through a succino-dehydrogenase preparation from pork heart for 2½ hours, a decrease in enzyme activity ranging from 9 to 50 per cent occurred. This effect was irreversible. Lehmann (1935) made the observation that at pH of less than 7.4 the oxygen utilization by a succinic acid-succinic dehydrogenase system was not inhibited by almost pure oxygen (713 mm. tension), while at pH greater than 7.4, the oxidation was inhibited. The toxic effect of the oxygen was exerted only in the presence of succinic acid and was irreversible.

Investigating the effect of pure oxygen on an entirely different kind of enzyme system, Kwan and Tung (1938) found that oxygen at atmospheric pressure slowed the rate of proteolysis in acid glycerol extracts from sheep liver.

Contribution No. 24 from the Biology Department, Brooklyn College, Brooklyn, N. Y.

That a relationship exists between growth and respiration (under the control of different enzyme systems) has now been clearly established for the oat coleoptile (Bonner, 1933, 1933a, 1936; Commoner and Thimann, 1941; Albaum and Commoner, 1941). The present investigations were undertaken in an attempt to explain the inhibitions in the growth of oat seedlings due to exposures to oxygen in terms of an analysis of several known enzyme systems. The activity of three enzyme systems was investigated: cytochrome oxidase, catalase and dehydrogenase.

MATERIAL AND METHODS.—Grains of *Avena sativa* L. var. *Fulghum* similar to those used in earlier experiments were hulled and soaked in distilled water with either continual oxygenation or aeration for twenty-four hours at room temperature. After the treatment, the grains were planted in beakers in contact with moist filter paper, as described in an earlier paper (Kaiser and Albaum, 1939). The plants were then allowed to continue their growth in the dark at 27°C. At various intervals the coleoptiles were measured to the nearest millimeter under an orange safe-light. Coleoptile length was used as an index of growth. All figures reported are the averages of at least twenty plants.

The first experiments on enzyme activity were carried out with extracts which were prepared in the following way. Grains treated in the above manner were removed from the beakers after thirty hours (total age from time of soaking—fifty-four hours). The embryos were carefully dissected from fifty seedlings, ground in sand in 2 cc. of M/15 phosphate buffer (Na_2HPO_4 , KH_2PO_4), pH 7.4, and taken up in 3 cc. of additional buffer. After light centrifugation the supernatant fluid was decanted and stored in the ice chest overnight. In all cases where "extract" is spoken of, reference is made to the supernatant fluid after one day's storage in the ice chest.

Cytochrome oxidase activity was determined by measuring the oxygen consumption of extracts in the presence of paraphenylene diamine (.433 g./100 cc.) and cytochrome C in a Warburg respirometer at 26°C. The usual procedure was to use 0.4 cc. of extract, 1.0 cc. of paraphenylene diamine, 0.2 cc. of cytochrome C, and 0.4 cc. of M/15 phosphate buffer. The cytochrome C was prepared from beef heart by the method of Keilin and Hartree (1937).

Catalase activity was ascertained by measuring the oxygen evolved by the extract acting upon a given quantity of hydrogen peroxide in a Warburg respirometer. The kinetics of the reaction were studied, and the time required to decompose half the peroxide was calculated from the time curve. The shorter the half time, all other factors being constant, the greater the enzyme activity. The usual procedure involved the use of 0.2 cc. of extract, 0.2 cc.

of 3 per cent hydrogen peroxide, and 1.6 cc. of M/15 phosphate buffer.

Dehydrogenase activity was studied by the Thunberg methylene blue technique. The addition of succinate produced no change in decolorization time, so that it was not used in any of the experiments re-

ported on. What, therefore, was being measured was dehydrogenase acting upon endogenous substrate. The side arms of the Thunberg tubes contained 0.5 cc. of extract, while the main vessel contained 0.5 cc. of methylene blue (M/15 phosphate buffer, pH 7.4—3 parts, .0004 M methylene blue—4 parts), and 0.5 cc. of M/15 phosphate buffer. After the tubes were evacuated for three to five minutes, they were placed into a 37.5°C. incubator and allowed to come to temperature equilibrium. The contents of the side arm were then tipped in. In the early experiments the time for complete decolorization was used

as an index of enzyme activity. In later experiments, the kinetics of the decolorization reaction were studied with an Evelyn photoelectric colorimeter, and the time for half decolorization, read from the time curve, was used as a measure of rate. Experiments carried out at 26° gave similar results.

Increase in total nitrogen in aerated embryos (closed circles) and oxygenated embryos (open circles) with time.

ported on. What, therefore, was being measured was dehydrogenase acting upon endogenous substrate. The side arms of the Thunberg tubes contained 0.5 cc. of extract, while the main vessel contained 0.5 cc. of methylene blue (M/15 phosphate buffer, pH 7.4—3 parts, .0004 M methylene blue—4 parts), and 0.5 cc. of M/15 phosphate buffer. After the tubes were evacuated for three to five minutes, they were placed into a 37.5°C. incubator and allowed to come to temperature equilibrium. The contents of the side arm were then tipped in. In the early experiments the time for complete decolorization was used

In some of the experiments oxygen consumption measurements were made on intact embryos. These were also done in the Warburg respirometer and are recorded on a per embryo as well as on a dry weight basis. In order to carry out methylene blue decolorization experiments on intact embryos without interfering with the operation of the colorimeter, the following procedure was employed. Intact embryos were placed in the side arms of the Thunberg tubes. The methylene blue solution from the main vessel was tipped into the side arm, and the whole tube was kept in an inverted position during the course of the

run. Readings were taken at intervals by tipping the solution back into the main vessel and recording the decolorization in the colorimeter.

In the course of the investigations assays on total nitrogen were carried out. These were done by means of a micro-Kjeldahl technique in the usual way.

NaNO_2 is then tipped in and allowed to react with the contents of the main vessel for one hour. Then the KMnO_4 is tipped in and the flasks are shaken until all the NO_2 is absorbed. This is completed in about five minutes. The difference before adding the NaNO_2 and after adding the KMnO_4 multiplied by

Fig. 5-8.—Fig. 5 (upper left). Oxygen consumption of intact embryos from aerated seeds (closed circles) and oxygenated seeds (open circles) at 48, 72 and 96 hours.—Fig. 6 (lower left). Decolorization of methylene blue as measured with the Evelyn photoelectric colorimeter by five intact control embryos.—Fig. 7 (upper right). Catalase activity of intact embryos from aerated seeds (closed circles) and oxygenated seeds (open circles) with time.—Fig. 8 (lower right). Increase in amino nitrogen in embryos from aerated seeds (closed circles) and oxygenated embryos (open circles) with time.

Amino nitrogen determinations were performed in the Warburg respirometer according to the method of Warburg, Christian and Griese (1935). In this method triple side arm flasks are used. Into the two connecting arms are placed 2 cc. of alkaline KMnO_4 (11 g. NaOH , 5 g. KMnO_4 , 89 cc. H_2O). The other side arm contains 0.4 cc. of NaNO_2 (9.8 g./100 cc.). Into the main compartment is placed the ground material to be tested in 1.8 cc. of water, together with 0.2 cc. of 33 per cent acetic acid. The vessels are then filled with nitrogen, transferred to the water bath at 26°C ., allowed to come to equilibrium without shaking and the manometers are read. The

the vessel constant and corrected for the blank (without the test material) is a measure of the amino nitrogen. One cu. mm. of gas evolved is equivalent to .000625 mg. of amino N.

EXPERIMENTAL.—GROWTH AFTER OXYGENATION AND AERATION.—The growth of *Avena* coleoptiles following exposure of grains during the soaking period to oxygen and air for twenty-four hours is shown in table 1 and figure 1. Also included are data on bubbling nitrogen through soaking grains in a similar way. Apart from an increase in the lag phase of the curve, the treatment with nitrogen produces no inhibition in growth. In fact, final coleoptile size is

TABLE 1. *Growth of grains of Avena sativa following soaking in distilled water for 24 hours through which air, oxygen or nitrogen has been bubbled.*

Time in hours	Coleoptile length in mm.

144.0	44.6	7.1	46.6

invariably larger after nitrogen treatment (for a discussion of this phenomenon, see Albaum, Kaiser and Eichel, 1940). The nitrogen treatment was carried out in order to rule out the possibility that the inhibition is due to the lack of CO₂ rather than to the presence of oxygen. In certain bacteria (Novak, 1908; Smith, 1924; Gladstone, Fildes and Richardson, 1935) carbon dioxide is necessary for growth. Bubbling carbon dioxide-free gas mixtures through culture media brings about growth inhibitions.

ENZYME ACTIVITY OF EXTRACTS.—Oxygen uptake of extracts.—The rates of oxygen consumption by extracts from treated and control embryos are presented in table 2 together with data on the addition

TABLE 2. *Oxygen consumption of extracts prepared from fifty embryos of aerated and oxygenated oat grains and sodium azide inhibition (extract—0.4 cc.; paraphenylene diamine [.433 g./100 cc.]—1.0 cc.; cytochrome C—0.2 cc.; M/15 phosphate buffer to final volume of 2.0 cc.). Temperature—26°C.*

of cytochrome C, paraphenylene diamine and sodium azide. It will be noted that the endogenous oxygen consumption of normal extract is very low and is increased more than five fold by the addition of paraphenylene diamine and cytochrome C. The endogenous oxygen consumption of the extract from oxygenated embryos, however, is high and is stimulated only slightly by the addition of paraphenylene dia-

mine and cytochrome C. Several possibilities suggest themselves. Either the high endogenous respiration is due to a system other than the cytochrome oxidase system which might lead to a failure to respond appreciably to the addition of cytochrome C and paraphenylene diamine, or the high respiration is due to the presence of substrate which has not been used up. Consequently, the addition of paraphenylene diamine might not produce any large increase in oxygen uptake. That the latter interpretation is probably correct is borne out by what happens when azide is added. Sodium azide, according to Keilin (1936), specifically poisons the cytochrome oxidase. It will be noted that when azide is added the respiration of both the oxygenated extract and the aerated extract are inhibited to about the same extent and brought down to approximately the same level, suggesting the operation of the cytochrome oxidase system in both cases. It appears, therefore, that at least after thirty hours following treatment the cytochrome oxidase activity in aerated and oxygenated extracts is approximately the same; if anything, the activity of the oxygenated extract is slightly higher.

Catalase activity.—The results of a typical run on aerated and oxygenated extract in testing for catalase activity are given in figure 2 and table 3. It will

TABLE 3. *Catalase activity of extracts prepared from embryos of aerated and oxygenated oat grains (extract—0.2 cc.; H₂O₂ [3 per cent]—0.2 cc.; M/15 phosphate buffer—1.6 cc.).*

II	{ 1.4 1.4	2.9 2.8

be noted that oxygen is evolved more rapidly by the aerated extract than by the oxygenated one. When half times are computed, it is apparent that the rate of peroxide breakdown is about twice as rapid in the control. There is then a clear cut difference in catalase activity following aeration and oxygenation.

Dehydrogenase activity.—The rates of methylene blue decolorization by treated and control extracts are shown in table 4. From this it is apparent that, just as in the case of catalase activity, oxygenated extracts show a lower dehydrogenase activity than aerated ones.

THE NITROGEN CONTENT OF SEEDLINGS.—The question now arises: does the oxygen treatment lead to the inactivation of enzyme already present in the embryo, or does oxygen prevent the formation of enzyme by the embryo? A study of the literature seems to indicate that in growing seedlings enzyme activity develops with time. Thus, Olcott and Thornton (1939) found that in cottonseeds the catalase content of whole seeds increased from 120 to 140

TABLE 4. *Dehydrogenase activity of extracts prepared from embryos of aerated and oxygenated oat grains (extract—0.5 cc.; methylene blue [M/15 phosphate buffer, pH 7.4—3 parts, .0004 M methylene blue—4 parts]—0.5 cc.; M/15 phosphate buffer—0.5 cc.).*

per cent in the first forty-eight hours of germination. Deleano, Popovici and Ionesco (1937) found that in wheat, oat and corn seedlings the catalase content increases for about the first ten days of growth, then decreases slightly and remains about constant. In germinating barley, von Euler, Myrbäch and Myrbäch (1930) reported that the catalase activity increases and reaches a maximum on about the eleventh day. The same is reported for proteinases in wheat by Mounfield (1936) and for peptidases in the soy bean by Stakheeva-Kaverzneva and Oleiknikova (1936).

Valy and Pokary (1939) made the significant observation that the catalase content of wheat is proportional, among other things, to the amount of nitrogen in the nutrient. In comparing extracts from experiment to experiment, the authors of this paper felt that they could best be compared in terms of total nitrogen, so that micro-Kjeldahl determinations were carried out on 0.2 cc. portions of extract routinely. In every case the total nitrogen of normal extracts was much higher than that of oxygenated extracts. In one typical case, 0.2 cc. of normal extract contained 0.236 mg. total nitrogen, while 0.2 cc. of oxygenated extract contained 0.047 mg. total nitrogen, or a five-fold difference. It was, therefore, decided to investigate the nitrogen content of embryos and endosperms as growth proceeds, in order to ascertain any differences which might arise following aeration and oxygenation and to correlate such results with the enzyme data.

Grains, weighing between 30 to 35 mg., were aerated and grown in beakers in the usual way. At

different intervals, plants were removed, embryo carefully separated from endosperm and total nitrogen determined for each. The results are shown in table 5 (upper part) and on figure 3 (expressed on

a per cent basis). It will be noted that the total nitrogen in the whole seedling remains relatively constant, but that with time the nitrogen content of the embryo increases at the expense of endosperm, suggesting that nitrogen moves from the endosperm to the embryo as growth proceeds.

When the same procedure is followed with seedlings from grains which have been oxygenated, one gets the data shown in table 5 (lower part). First it will be noted that the nitrogen content of the whole seedling remains fairly constant, as before, but that the figure is lower than that for aerated seeds. This

96	.0262	.0299	.0065	.0154

difference may or may not be significant. What is more important, however, is that for a time the nitrogen content of the embryo increases slightly and then ceases to increase, while the endosperm loses a little nitrogen and then stops losing it. If the nitrogen data for aerated and oxygenated embryos are plotted together (fig. 4) and compared with the growth curves shown in figure 1, the similarity at once becomes apparent. There is a correlation, then, between the movement of nitrogen and growth. The same kind of nitrogen transport in normal plants is suggested by the work of Bonnet (1929) in *Lupinus*, by Echevin and Brunel (1937) also in *Lupinus*, and in *Lathyrus* by Isaac (1938).

THE DEVELOPMENT OF ENZYME SYSTEMS IN AERATED AND OXYGENATED EMBRYOS.—*Cytochrome oxidase activity*.—The oxygen consumption of extracts from oxygenated and aerated grains is not appreciably different at least up to four days of growth, when tested with paraphenylene diamine and cytochrome C. Yet when the oxygen uptake of intact embryos is measured in the Warburg respirometer, one obtains results shown in figure 5. The increase in oxygen uptake at 48, 72 and 96 hours in normal embryos is similar to the normal growth increase (see fig. 1). The increase in oxygen uptake in treated embryos also corresponds to the growth increase. There would appear to be a correlation between rate of oxygen uptake with time, growth and nitrogen transport. To test the possibility that the oxygenated embryos respire less because they are smaller, the above data have also been calculated on a dry weight basis. The data are shown in table 6. Even on a dry weight basis the aerated embryos respire more rapidly than oxygenated ones. It is also interesting to

note that the rate of oxygen uptake on a dry weight basis remains approximately the same at 48, 72 and 96 hours.

Dehydrogenase activity.—If it is true that the cytochrome oxidase activity of normal and treated extracts is about the same up to about four days, how is one to account for the differences in oxygen uptake by intact embryos during the same interval? The most likely possibility is that the oxygen uptake of the intact oxygenated embryos is lower because of lower dehydrogenase activity. A depression in the dehydrogenase end of the respiratory cycle will depress the activity of the oxidase end. That dehydrogenase activity is lower in oxygenated extracts has already been demonstrated (table 4).

In this portion of the work dehydrogenase activity was assayed on intact plants using the Evelyn photoelectric colorimeter to measure methylene blue decolorization. A typical run with five normal embryos is shown in figure 6. The time for half decolorization as read from the curve was used as an index of enzyme activity. The results with oxygenated and aerated embryos are summarized in table 7. It will be noted that the rate of decolorization is only slightly more rapid at 48 hours in aerated embryos, but that the rate changes abruptly at 72 and 96 hours. The rate of decolorization of oxygenated embryos increases, but not as much as the controls, and attains a maximum rate at about 72 hours, corresponding to the time at which nitrogen has ceased to move across from the endosperm. There appears to be a correlation thus far between growth, nitrogen transport, rate of oxygen uptake and dehydrogenase activity.

Catalase activity.—Catalase activity was assayed as before with extracts made at 24, 48, 72, 96 and 120 hours. The results are shown in figure 7. It will be noted again that there is a parallelism between growth, rate of oxygen consumption, dehydrogenase activity, nitrogen transport and now catalase activity. It also appears from figure 7 that up to about 96 hours the rate of enzyme development in oxygenated embryos is lower than that of normal embryos, but that at 120 hours there is no longer development but destruction of enzyme activity as well. From other experiments the same phenomenon is observed for dehydrogenase activity.

PROTEIN BREAKDOWN IN THE ENDOSPERM.—Thus far it appears that the chief effect of the oxygen treatment has been to produce some kind of irreversible change which manifests itself in the failure of most of the nitrogen to move from endosperm to embryo. Correlated with this failure of nitrogen to be transported is a corresponding slowing down in the rate of catalase and dehydrogenase production. All these in turn are correlated with the failure of plants treated in such a manner to grow normally.

What occurs in the endosperm to prevent nitrogen from moving across to the embryo? That the effect is probably not due to an elimination of CO₂ and a consequent upset in the carbonate buffer systems is indicated by the nitrogen growth curve in figure 1, where

CO₂ is presumably washed out as effectively as with oxygen. Apart from an increase in the lag phase of growth, plants treated in such a way attain at least normal size.

In the seed, between 85 and 90 per cent of the nitrogen is protein nitrogen (Bonnet, 1929; Isaac, 1938). Since the embryo contains only a small portion of the total nitrogen of the seed before growth occurs, it is safe to say that most of the protein occurs in the endosperm. It is also safe to say that, before the nitrogen can be transported from the endosperm to the embryo, the large protein molecule must be broken down to a more soluble form, i.e., amino or amide nitrogen. One might, therefore, expect to get an increase in amino nitrogen in the embryo at the same time that total nitrogen is decreasing in the endosperm. That this kind of phenomenon occurs is shown by the data in tables 5 (upper part) and 8 (I). It will be noted that as total nitrogen in the endosperm decreases, the amino nitrogen in the embryo increases. The amino nitrogen in the endosperm appears to remain constant, which probably means that an equilibrium in breakdown is maintained, the excess amino nitrogen being continually transferred to the embryo. In plants which have been oxygenated the total nitrogen in the endosperm decreases only slightly. In the embryo (table 8, II), there is less amino nitrogen, suggesting that protein breakdown in the endosperm is also occurring more slowly. This is borne out by the figures from oxygenated endosperms where there is always less amino nitrogen than in normal endosperms of the same age. It will be noted, too, that whereas the amino nitrogen in normal embryos increases more than fifteen fold between 48 and 96 hours, in oxygenated embryos the increase is only three fold. The data for amino nitrogen increase are shown graphically in figure 8. Again there appears to be a correlation between all the phenomena studied: growth, total nitrogen transport, rate of oxygen uptake, dehydrogenase activity, catalase activity and finally movement of amino nitrogen.

GENERAL DISCUSSION.—The data seem to indicate, then, that all of the phenomena noted may be due to the failure of the protein in the endosperm to break down. This would prevent nitrogen transport, which in turn may prevent the development of the different enzyme systems, and consequently prevent growth. The exact mechanism by which oxygen may produce its effect on nitrogen breakdown is not clear. It may be due to a direct effect on proteolysis (Kwan and Tung, 1938) or on the development of proteolytic enzyme activity in the endosperm.

Another possibility suggests itself. The protein breakdown may be prevented by the failure of the amino nitrogen to move across into the embryo. That is, proteolytic enzymes may be present in sufficient quantity, but there may be something wrong with the mechanism which accounts for moving the nitrogen through the cotyledon into the embryo. One might not expect the protein breakdown to occur continu-

ously unless the end products of the breakdown are removed.

That the phenomenon may not be due simply to the failure of nitrogen to move from endosperm to embryo is suggested by some preliminary results which indicate that auxin also is not transported when grains have been treated with oxygen.

Additional experiments to elucidate further the phenomenon are now under way.

SUMMARY

When grains of *Avena sativa* are oxygenated during the soaking period, subsequent growth is almost completely inhibited as compared to aerated controls.

Enzyme assays carried out on extracts thirty hours after oxygenation indicate little or no change in cytochrome oxidase activity, a lowered catalase activity and lower endogenous dehydrogenase activity.

In the course of normal development, nitrogen moves from endosperm to embryo. The increase in embryo nitrogen follows the course of growth. In plants grown from oxygenated grains, nitrogen increase in the embryo occurs more slowly for a time and then stops. This behavior is correlated with the same type of growth pattern.

In the case of catalase it is shown that oxygenation at first slows down catalase activity and later causes catalase destruction.

The development of catalase and dehydrogenase activity in intact embryos seems to be correlated with the movement of nitrogen from the endosperm to the embryo in both normal and oxygenated grains.

The failure of nitrogen to move from endosperm to embryo in oxygenated plants does not appear to be due to the mechanical removal of carbon dioxide by pure oxygen, since nitrogen gas produces no comparable inhibition in growth.

In plants grown from oxygenated plants, amino nitrogen is lower in embryo and endosperm, suggesting that oxygen may interfere with proteolytic breakdown in the endosperm and, consequently, prevent nitrogen transport, the development of enzyme activity and finally growth.

LONGEVITY OF SUGARCANE AND CORN POLLEN—A METHOD FOR LONG-DISTANCE SHIPMENT OF SUGARCANE POLLEN BY AIRPLANE¹

George B. Sartoris

A study of pollen longevity and the means of extending it is important not only because it makes possible the shipment of pollen over great distances, so that plants separated by thousands of miles may be crossed, but it also makes it possible to bridge over long intervals separating the flowering of different forms which one may desire to cross. The purpose of this study was to find a method of storing and packing sugarcane pollen for long-distance shipments by air in order to cross a cold-resistant, Temperate Zone wild sugarcane, *Saccharum spontaneum* L., which does not flower in the Tropics, with the large cultivated tropical sugarcane.

The wild cane was growing at Arlington Experiment Farm, Rosslyn, Virginia, near Washington, D. C., and flowered during July and August (Brandes *et al.*, 1939). Since cultivated sugarcanes in the Northern Hemisphere flower during late autumn and winter, it was necessary, in order to make the cross, to ship the pollen of the wild cane to the

Southern Hemisphere where the seasons are reversed. The first successful pollen shipments were made during the summer of 1938. In addition, Brandes (1939) successfully transported living plants of the wild cane in the early flowering stage from Washington, D. C., to Colombia, South America, by steamer.

—Andronescu (1915), Anthony and Harlan (1920), Knowlton (1922), Holman and Brubaker (1926), Kempton (1936), and Bair and Loomis (1941) have shown that the pollen of Gramineae has a very short life span. Under the normal conditions of temperature and humidity existing at the time of flowering, the pollen remains viable for only a few hours. Vijayasarahy (1939) kept sugarcane pollen viable for two days in a thermos bottle charged with ice and water. At the end of two days a suitable recharging was needed. There is general agreement among investigators that death of the pollen of grasses is due to loss of water and that duration of

¹ Received for publication October 29, 1941.

life is longer at fairly low temperatures and high relative humidities.

Failure of germination of the pollen of Gramineae on artificial media is a common difficulty. Apparently the water relations are very delicate, and the concentration has to be exactly correct before germination takes place. Venkatraman (1922) working with sugarcane pollen obtained the best germination on a medium of 0.7 per cent agar with 26 per cent sucrose. Knowlton (1922) obtained good germination of corn pollen on 0.7 to 1 per cent agar plus 15 per cent sucrose. The results were not constant. At times germination from a certain concentration was excellent, and on repetition the same strength of solution failed to induce germination. Bair and Loomis (1941) obtained as much as 90 per cent germination of corn pollen on a solution containing 0.7 per cent agar and 15 per cent sucrose at a temperature of 23°C. and 90 per cent relative humidity. With different lots of highly viable pollen the sucrose percentage showing maximum germination varied between 10 and 15 per cent. They stress the importance of sowing the pollen as soon as the medium has solidified. Best results were obtained when the pollen grains were two-thirds embedded in the medium. Germination improved with storage for about six hours, then declined rapidly. However, one lot of pollen was viable after ten days' storage at 8°C. Longer storage life was obtained at higher humidities, but many lots stored in nearly saturated air suddenly became moist and clumped together and thereafter showed no germination.

MATERIALS AND METHODS.—For experimentation at different temperatures the pollen was stored in a constant temperature chamber adjusted to 15°C. This temperature was controlled to within $\pm 0.5^\circ\text{C}$. Household electric refrigerators were used to obtain the storage temperatures of 7°C. and 4°C. Since the refrigerators were opened only once a day, when the pollen was tested for germination, the temperatures were controlled to within 1°C. The relative humidities were obtained by using saturated solutions of different salts. It was assumed that the relative humidity over water was 100 per cent. Sulphuric acid solutions were tried in a few experiments, but germination was adversely affected even at the lower concentrations (higher humidities).

To obtain the sugarcane pollen that was used in the experiments several tassels were gathered late in the afternoon and taken to the laboratory, where the stems were placed in a solution of 0.2 per cent sulphurous acid and 0.2 per cent ortho phosphoric acid, and the tassels were inclined over a large piece of plate glass. The following morning the tassels were tapped, and the pollen settled on the glass. The pollen was then swept up and screened through a 50-mesh copper screen to remove the anthers and stigmas that had fallen with the pollen. The few stigmas that remained were removed by placing the pollen on a sheet of stiff paper, inclining the sheet and tapping it lightly. The stigmas remained behind, while the pollen was gathered on another sheet of

paper. Ten or twelve tassels yielded from 15 to 30 grams of pollen for three or four successive mornings. Golden Cross Bantam corn (*Zea Mays*) pollen was gathered early in the morning from a field on Arlington Experiment Farm.

Weighed amounts of pollen were placed immediately in small chambers, which were maintained at different relative humidities, and stored in the refrigerator. The chambers were glass stoppered bottles of about 300 ml. capacity, in each of which there were 80 ml. of a saturated salt solution, a different solution for each degree of humidity. The pollen was placed in shallow vials which were suspended from the stopper. Other small chambers were made from test tubes. The shallow vials containing the pollen were suspended in the test tube by linen threads, and the threads were held securely in place by the rubber stopper used to close the tube. The germination of the stored pollen was tested each morning.

The viability of the sugarcane pollen was tested by germination on artificial medium composed of 1.5 per cent agar and 25 per cent sucrose, and that of the corn pollen on 1.5 per cent agar plus 18 per cent sucrose. Various concentrations of sugars from 10 to 45 per cent were tried, but the above concentrations gave the maximum germination for the cold-resistant wild sugarcane and Golden Cross Bantam corn, respectively. The agar was cooled to about 60°C. and poured into Petri plates or a layer about 1 mm. thick was spread on microscopic slides. Both the Petri plates and the slides gave satisfactory results, but the slides were more convenient to use. As soon as the agar jelled the pollen was dusted on from a scalpel. The slide was then held in a horizontal position and the edge tapped sharply with a pencil to break up lumps and to spread the pollen evenly over the surface of the agar. The slides were placed in a moist chamber which was only moist enough to prevent condensation on the slides. Germination at room temperatures, which ranged from 22° to 30°C., began in two to three minutes. Growth of the pollen tubes was very rapid, attaining a length of 200 to 400 microns in twenty to thirty minutes.

When artificial media are used for germination of sugarcane and corn pollen there should be no free moisture on the surface of the agar. When Petri plates were used, they were left uncovered until the agar had set and cooled to room temperature, so that there was no condensation when the plates were covered. Condensation water on the surface of the agar causes the pollen grains to burst.

RESULTS AND DISCUSSION.—The investigation of pollen storage at 7°C. consisted only of a study of the effect of temperature on the pollen longevity. Several experiments were made with the pollen from plants of the clone 59 Amu Darya (*S. spontaneum*). The pollen was placed in vials closed with cotton plugs. There was some variability in the length of time the pollen remained viable, but in all experiments there was good germination at the end of seven days' storage, and in two experiments a few grains germinated after storage for ten days. After

TABLE 1. Germination of sugarcane pollen (U. S. 4523) stored at 4°C. and at relative humidities from 39 to 100 per cent, August 22, 1940.

^a Good = 70 to 90 per cent. Germ tube grew four to five times diameter of pollen in twenty minutes.

^b Fair = 40 to 70 per cent. Germ tube grew four to five times diameter of pollen in twenty minutes.

^c Very poor = 10 per cent or less. Tube short, growth slow.

^d Poor = 20 to 40 per cent. Germ tube grew four to five times diameter of pollen in twenty minutes.

^e Pollen was in a cotton plugged vial, and humidity was not controlled.

three or four days' storage the pollen in the vials was moist.

The control pollen stored in cotton plugged vials at room temperature remained viable for twelve to twenty-four hours. Pollen that was spread out on a watch crystal in diffuse light in the laboratory remained viable for about six hours.

The results of the experiment at 15°C. and at relative humidities of from 39 to 100 per cent showed that this temperature was not favorable for prolongation of the life span. Pollen stored at 100 per cent relative humidity remained viable for three days, at 70 to 90 per cent for two days, and at humidities below 70 for one day.

The results of an experiment with the pollen of clone U. S. 4523 (*Saccharum spontaneum*), stored at a temperature of 4°C. and at relative humidities from 39 to 100 per cent, are given in table 1. Pollen stored at relative humidities of 39 to 52 per cent or over calcium chloride remained viable for one to two days; at 70 to 84 per cent the life duration was from four to six days, and at 90 to 100 per cent from eight to ten days, as indicated by the ability of the pollen to germinate on an artificial medium. Although high relative humidities increased the life span, the pollen became moist, in which state it was difficult to use for pollinating sugarcane flowers. The pollen stored at 90 per cent relative humidity was moist, and at 100 per cent it was so moist that it formed a stiff dough. The pollen in this state is a favorable medium for the development of fungi, and even at 4°C. after several days' storage there may be a considerable growth of mycelium penetrating the mass of pollen. At relative humidities of 70 to 84 per cent

the pollen has the appearance of coarse corn meal, owing to pollen grains adhering together to form clumps. However, even after storage for from six to eight days about half of the pollen was still dry and in a satisfactory physical state for making pollinations. Pollen stored at 50 per cent relative humidity or lower was a dry powder, but under such conditions it retained viability for a very short period. The pollen marked "control" was in a cotton plugged vial. Although the humidity of the refrigerator varied between 50 and 60 per cent, the humidity in the vial was much greater, as indicated by the pollen becoming moist. Since the longevity and the moisture of the control pollen was about the same as pollen stored at 90 per cent humidity, the relative humidity in the vial was about 90 per cent.

The pollen stored at room temperatures, which during July and August ranged from 22° to 35°C., had a short life span. At a relative humidity of 100 per cent the pollen was viable at the end of the second day of storage, and at lower humidities the life span was less than one day.

The results of experiments with sugarcane pollen stored in vacuum at 4°C. were extremely variable. When the pollen occupied one-half or more of the volume of sealed glass tubes there was no germination after storage for twenty-four hours. The moisture excreted by the pollen turned it into a doughy mass. When a small amount of pollen was sealed in a tube, there was good germination after two days' storage and a few grains germinated after four days.

The best results were obtained by using a large tube, a relatively small amount of pollen, and calcium chloride to absorb part of the water excreted by

the pollen. A bulb was blown at the end of a tube about 30 cm. long and 20 cm. diameter, and 2 grams of CaCl_2 were put in the bulb. The tube was bent at the middle to a right angle, and a bulb was blown near the open end. The open end was drawn down to a diameter of about 2 to 3 mm., and 2 gms. of pollen were placed in the empty bulb. After evacuating with a high-vac pump for thirty minutes, the tube was sealed. Two tubes were stored at 4°C . and one at room temperature. The pollen stored at room temperature failed to germinate when tested after two days' storage. One of the tubes stored at 4°C . was opened after four days' storage and the germination was as good as fresh pollen. The other tube was opened after eight days' storage and gave a germination of about 25 per cent, but growth was slow, so that only short pollen tubes were formed in twenty minutes. The experiments indicate that low pressure is not as favorable for storage as normal atmospheric pressure.

The behavior of the corn pollen was very similar to that of sugarcane pollen stored under the same conditions. The results of an experiment with the pollen of Golden Cross Bantam corn stored at a temperature of 4°C . and at relative humidities from 39 to 100 per cent are given in table 2. The life of the corn pollen was prolonged by low temperature and high humidity. At 90 and 100 per cent relative humidities the pollen was viable after ten days' storage. For the first six or seven days the germination and growth of the tubes of the stored pollen was as good as that of fresh pollen, but thereafter the percentage of germination dropped very rapidly so that, after seven or eight days of storage, less than 25 per cent of the pollen germinated, and growth of the pollen tube was very slow.

The results of these experiments show that the pollen of sugarcane and corn remained viable longest

under conditions of low temperature and high humidity. When sugarcane and corn pollen are exposed to normal atmospheric conditions or to low humidity, the degree of drying determines the duration of life. An excessive loss of water by the pollen is accompanied by a change in the physical state of the protoplasm. When pollen that had been stored for a day or longer at low humidities or over calcium chloride was placed on an agar medium, favorable for germination, the contents of the grains oozed out through the germ pores. This was not like the rapid movement or violent eruption of fresh pollen on a hypotonic medium. The slow oozing of coarse granular protoplasm a few seconds after the pollen was placed on agar indicates that some destructive change in the protoplasm has taken place. Nevertheless, the pollen can resist desiccation to a considerable degree without loss of vitality, as shown by storage at humidities of 70 to 84 per cent.

METHOD OF PACKING SUGARCANE POLLEN FOR LONG-DISTANCE SHIPMENTS BY AIRPLANE.—While the pollen retained its viability longest at a low temperature and high humidity, it became moist and caked, and this condition interfered with the mechanical operations of pollination. It was apparent, therefore, that it would be necessary to devise a method of packing that would keep the pollen viable and in about the same physical condition as fresh pollen. The storage experiments at humidities of 70 to 84 per cent showed that the pollen could resist considerable loss of moisture without loss of viability for four days, and that the pollen was dry enough for making pollinations; therefore, in the method adopted, calcium chloride was used to remove part of the moisture.

The pollen that was intended for shipment by airplane was gathered at about 9 A.M. from tassels that had been placed in the laboratory the night be-

^e The control was in a cotton plugged vial and humidity was not controlled.

fore. Vials of about 10 ml. capacity were filled half full with pollen, plugged with cotton, and dried in a desiccator over CaCl_2 for about two hours. Meanwhile, about 8 gms. of CaCl_2 were placed in a test tube (18 by 2.5 cm.), and the tube was closed with a rubber stopper. After drying for two hours, the vials containing the pollen were wrapped in cotton and placed in the test tube. The test tube was closed with a rubber stopper, placed in a precooled, wide-mouthed thermos bottle, and surrounded with moist peat that had been frozen. The thermos bottle was surrounded with ice caps and sections of automobile inner tubes filled with crushed ice. This was packed in a double-walled corrugated paper box of sufficient capacity so that the ice caps and thermos bottle were surrounded by about four inches of granulated cork. There were about six pounds of ice in each shipment. The ice caps were used because the shipments were by air express, and it was necessary that the ice be placed in watertight containers.

Solid carbon dioxide was tried, but it was not possible to control the temperature, and, at the temperature required, "dry ice" is not as efficient as ice.

On arrival at Palmira, Colombia, three days after packing, the vials of pollen were removed from the test tube and immediately placed in a refrigerator at 4° to 5°C . It was too late in the day to use the pollen on the date of arrival; therefore, pollinations were made the following morning and for two or three more successive mornings.

During the summer of 1939 eight shipments of pollen seedlings of 59 Amu Darya and 60 Amu Darya were made. These two clones of cold resistant *Saccharum spontaneum* are practically indistinguishable. However, 59 Amu Darya has 60 somatic chromosomes and 60 Amu Darya has 50 somatic chromosomes.

The pollen was used in crosses with P. O. J. 2725, a tropical commercial cane, and an abundance of fertile hybrid seed was obtained. Altogether the eight crosses made with the pollen shipped by air and the seven crosses made with the flowering plants of U. S. 4513 taken to Colombia by steamer produced more than 15,000 hybrid seedlings. The crosses made with the stored pollen produced as much viable seed as those made with fresh pollen from the plants of U. S. 4513. In August, 1940, two shipments of pollen of U. S. 4536, a selfed seedling of 59 Amu Darya, were sent to Colombia by air and used to pollinate P. O. J. 2725. About 3,000 hybrid seedlings were obtained. The ability of sugarcane pollen stored from four to

seven days to fertilize shows that germination on an artificial medium is a test of the ability of sugarcane pollen to function normally.

The hybrids are intermediate in stalk diameter, leaf width, and time of flowering. The male parent flowers in June and July in Louisiana, and a few flowers have been produced at the U. S. Sugar Plant Field Station, Canal Point, Florida, in June. At this station, however, growth is not normal, and it is only occasionally that some of the plants flower. The female parent at Canal Point, Florida, flowers in November–December. At Canal Point most of the hybrids flowered during August and September. In sucrose content and winter hardiness the hybrids tend more towards P. O. J. 2725.

SUMMARY

The maximum germination of the pollen of cold-resistant clones of *Saccharum spontaneum* was obtained on a medium composed of 1.5 per cent agar and 25 per cent sucrose.

The maximum germination of Golden Cross Bantam corn, *Zea Mays*, pollen was on a medium of 1.5 per cent agar and 18 per cent sucrose.

At temperatures from 22° to 30°C ., 80 to 90 per cent of fresh pollen germinated. Germination began in two or three minutes and growth of the pollen tube was very rapid.

Other conditions necessary for germination are that there must not be any free water on the surface of the medium, that the pollen be sown as soon as the agar gels, and that the cultures be kept in a moist atmosphere to avoid drying of the pollen.

Sugarcane and corn pollen remained viable for ten days when stored at 4°C . and relative humidities from 90 to 100 per cent. During the first six to seven days of storage, the germination was as good as that of fresh pollen.

A method of packing sugarcane pollen for long-distance shipments by air is described. Pollen of a cold-resistant wild sugarcane was shipped from Washington, D. C., to Palmira, Colombia, South America, where it was used in crosses with tropical commercial sugarcanes. An abundance of fertile hybrid seed was obtained.

Sugarcane pollen stored for four to seven days retained its ability to fertilize.

A QUANTITATIVE MORPHOLOGICAL ANALYSIS OF LARGE AND SMALL LEAVES OF ALFALFA, WITH SPECIAL REFERENCE TO INTERNAL SURFACE ¹

Franklin M. Turrell

HILL AND Thomas (1933) observed that, when leaves of alfalfa (*Medicago sativa* L.) were subjected to sulphur dioxide gas, large leaves were more readily injured than small leaves, and that neither type was injured near the veins. Zimmerman and Crocker (1934) reported similar responses in leaves of alfalfa and of several other plants.

Large leaves of *Catalpa speciosa* Warder have been shown to have greater internal-external surface ratios than smaller leaves of catalpa grown under the same conditions, and palisade tissue of leaves has been shown to expose more surface per unit volume than sponge tissue (Turrell, 1936). The extent of an absorbing area is known to be one of the factors limiting the rate of absorption of gases (Adeney and Becker, 1919, 1921).² It seemed possible, therefore, that the greater degree of injury to the large leaves of alfalfa might be related to larger internally exposed surfaces in these leaves, and that smaller internally exposed surfaces in the region of the veins of the larger leaves, as well as in the intervacular interval of smaller leaves, might be related to immunity.

Brown and Escombe (1900), in studies on the static diffusion of gases in relation to the assimilation of carbon and translocation in plants, found that the dimensions and distribution of small apertures influenced the rate of diffusion. Differences in the dimensions and distribution of stomata in large and small leaves of alfalfa might be expected, with resulting differential diffusion of sulphur dioxide; this might account for the different degree of injury in the two types of leaves. Under conditions causing closure of the stomata, injury to the alfalfa leaf might be effected either by gas penetrations of the cuticle and epidermis or by the quantity of gas trapped in the intercellular spaces.

As more sulphur seems to be excreted by roots of fumigated plants than by those of nonfumigated

plants (Thomas and Hill, 1937), it is evident that some form of sulphur ion is transported to the veins. The distance the sulphur radical is transported through the chlorenchyma may be related to susceptibility to sulphur dioxide injury. A thorough discussion of the relation of the intervacular interval to translocation in the leaf has been presented by Wylie (1939).

The present study on the quantitative morphology of alfalfa leaves is an outgrowth of interest in the responses of alfalfa leaves to sulphur dioxide gas.

The author became interested in this problem through Dr. George R. Hill, Jr., of the American Smelting and Refining Company, and wishes to express grateful appreciation to him for his unfailing kindness and for supplying the leaf samples and the outline drawings of the leaflets and stems used in these studies. Appreciation is expressed, also, to the American Smelting and Refining Company for supplying the grant which made the initiation of this work possible; to Professor R. B. Wylie for his helpful suggestions with respect to leaf structure; to Professors R. A. Fisher, G. W. Snedecor and Gertrude Cox, and to Dr. A. E. Brandt for advice with respect to statistics; and to Professor E. T. Bartholomew, Head of the Division of Plant Physiology of the University of California Citrus Experiment Station, where a portion of this work was completed.

MATERIALS AND METHODS.—Alfalfa plants for these studies were obtained from plots used for sulphur dioxide experiments by the American Smelting and Refining Company at Salt Lake City, Utah. Each plot contained twenty plants (Utah, common variety alfalfa). Four control plots were chosen because of the uniform growth of plants in these plots. Four plants similar in size and growth were picked—one from each plot; and from each plant, one of its several stems was selected. Diagrammatic drawings of these four stems, in figure 1, show the position of the leaves selected. The plants were near maturity and were from the second crop.

The first leaves to be developed on the main stem are classed as early primary leaves; those developed on the main stem later, that is, near the top, are classed as late primary. When the axillary bud from a primary leaf starts to grow, it puts out a shoot having leaves classed as secondary. On the basis of an

¹ Received for publication October 21, 1941.

² The equation for the rate of solution of gases in liquids is

$$\frac{dw}{dt} = SAp - \frac{fAw}{V},$$

where S = initial rate of solution per unit area, f = coefficient of escape, A = surface area, V = liquid volume, p = gas pressure, w = weight of gas involved, and t = time.

classes were selected from each stem as shown in table 1. The leaves were rapidly outlined, and one leaflet of each triad composing the leaf was selected. Leaves one square centimeter in area were arbitrarily classed as large leaves; those smaller in area were classed as small leaves.

A block of tissue 0.25 cm. square was cut from the center of the blade, as shown in figure 2, and killed in formalin-acetic acid-ethanol mixture. Twenty-four hours later the leaves were transferred to n-butyl alcohol solutions (Zirkle, 1930), dehydrated, and finally imbedded in paraffin. Transverse and tangential sections were cut 12 microns thick. Subsequently, the sections were stained in Delafield's hematoxylin and safranin, and mounted permanently.

All microscopical measurements and camera lucida drawings (used for chartometer and planimeter measurements) were made from these prepared slides. Measurements and drawings were made of tissue chosen at random on the slide and are representative of small regions in the central or near-central portions of the blade only (fig. 2).

Measurement of leaf area.—The penciled tracings of the selected leaflets were measured with a planimeter. Duplicate readings were made which checked within 0.02 square inches.

Measurement of internal surface.—The calculation of the ratio R (the internal surface of the leaf bordering intercellular space, measured in square microns, divided by a unit of external surface) was made with a slight modification of the method outlined by the author in an earlier paper (Turrell, 1936).

Fig. 2. Outline drawings of the leaflets of the twenty alfalfa leaves selected for these studies, showing the relative size of the leaflets, the leaflets sampled, and the positions from which the samples were taken.

Irregularity in the length of the palisade layers made it undesirable to measure each layer separately; the tissue was, therefore, handled as a unit. To distinguish the area of the internal surface of the palisade tissue thus determined, from determinations made by the original method (Turrell, 1936), the notation $l' p'$ was adopted. The presence of a layer of palisade-like tissue lying along the lower epidermis required the addition of measurements $l_1' p_1'$ which were made from camera lucida drawings in the usual manner.

Estimated internal surface in the vein region.—The vertical diameters of the major veins were measured from the transverse leaf sections. An average of these values was substituted for d_{va} in the formula given below. Similarly, the vertical diameters of the minor veins were obtained, averaged, and substituted for d_{vi} . By the use of these values and d_s (the thickness of the sponge parenchyma tissues), l' , l_1' , and R (the internal-external surface ratio for the leaf tissue within the intervacular interval), R_{va} (the internal-external surface ratio in the region of the major veins) and R_{vi} (the internal-external surface ratio of the tissue in the region of the minor veins) were calculated from the formulas:

$$(1) R_{va} = R - R \frac{d_{va}}{l' + l_1' + d_s}$$

$$(2) R_{vi} = R - R \frac{d_{vi}}{l' + l_1' + d_s}$$

Size of vein islets.—Measurements of vein islets were made on tangential sections. A microscope fitted with a 30 \times objective and 12 \times ocular was used in determining the diameters of the intervacular interval (the distance between minor veins). The

measurements were made inclusive of the border parenchyma and extended from vein edge to vein edge. Both length and width were included. Accuracy of approximately 2.27 microns could be obtained, but since the vein islets were of various shapes, ranging from triangles to irregular trapezoids, the significance of accuracy of the optical system may be minimized. The most consistent conformation was the rectangle. All measurements were made from the midpoint on any side to the midpoint on the opposite side.

Size of stomatal pores.—Pore measurements were made on camera lucida drawings of tangential sections of leaves. The microscope was fitted with a 91 \times oil-immersion objective, and a 10 \times ocular. Estimated accuracy was 0.1 micron.

Stomatal density.—Stomatal density was determined from tangential leaf sections. A microscope equipped with a high, dry, 62 \times objective and a 12 \times ocular was used. The diameter of the field was measured by the use of a stage micrometer. One hundred and fifty-five counts were made in the upper epidermis.

Size of epidermal cells.—Epidermal cell size was estimated from camera lucida drawings of the upper epidermal portions included in tangential sections. The drawings were made with a 10 \times ocular and 47.5 \times objective. Areas of ten cells were measured with a planimeter. The small subsidiary cells adjacent to stomata were never included. Samples of the remaining cells were taken at random for measurement.

Tissue thickness.—Tissue thickness was measured with a 40 \times or 90 \times objective (according to the size of the tissue) in combination with a 10 \times ocular and an ocular micrometer. Good accuracy was obtained for the 10 to 20 samples taken per leaf. Measurements were made from transverse sections.

RESULTS.—Reference to table 2 shows that the mean leaf area of the group of leaves classed as large was greater than that of the group classed as small, and that the mean value of the internal-external surface ratio in the intervacular interval was greater for the leaves of large leaf area than for those of small leaf area.

The mean areas of the leaves grouped according to origin, in square centimeters, are shown in table 3.

Estimations of the internal-external surface ratios in the regions of both major and minor veins are given in table 2. It should be noted (1) that the internal-external surface ratio in the region of the major vein of both large and small leaves is lower than the ratio in the intervacular interval or in the region of the minor veins of these leaves, and (2) that the internal-external surface ratio in the region of the major vein of the large leaves is lower than the internal-external surface ratio in the intervacular interval of the small leaves.

When the leaves were grouped according to origin, the early and late primary leaves had not only greater mean leaf area than the other leaf groups, but larger internal-external surface ratios in the

greatest in the intervacular interval (R), intermediate in the region of the minor veins (R_{vi}), and smallest in the region of the major veins (R_{va}).

Large leaves are thicker and have thicker upper and lower epidermis than small leaves (table 4 and fig. 3-7), but the percentage of total leaf thickness occupied by upper and lower epidermis is larger in small leaves (table 5).

Of the leaves classified according to origin, the early primary leaves were thickest, averaging 222.7 microns. Late primary leaves averaged 205.5 microns in total thickness; secondary leaves, 159.2 microns; tertiary leaves, 151.0 microns; and quaternary leaves, 135.5 microns. The average thickness of the upper epidermis of these leaf groups was 15.12, 13.50, 13.47, 12.05, and 11.40 microns respectively; that of the lower epidermis of the same leaf groups was 15.45, 12.72, 13.00, 12.75, and 11.42 microns, respectively.

Thickness of both palisade and sponge tissues was greater in large leaves than in small (table 4 and fig. 3-7).

16	5.42	50.4	38.2	6.19	19	5.81	46.8	41.6	5.81
17	6.35	52.3	35.7	5.76	20	7.09	38.4	46.5	7.76
Mean	7.15	49.6	36.2	6.87	Mean	8.25	42.6	40.3	8.72

The average thickness of the palisade tissue in the different leaf groups, in microns, was as follows: early primary, 112.30; late primary, 102.15; secondary, 73.25; tertiary, 67.52; and quaternary, 54.62. Thickness of sponge tissue in these groups averaged 80.05, 76.42, 59.20, 58.70, and 57.55 microns, respectively. Mesophyll thickness (that is, palisade thickness plus sponge thickness) in these groups of leaves averaged 192.25, 179.25, 132.25, 126.25, and 112.50 microns, respectively. The relative thicknesses of these tissues are shown in figures 3-7.

The percentage of leaf thickness occupied by palisade tissue was larger in large leaves than in small, while the percentage of sponge tissue was larger in small leaves (table 5). As may be readily calculated from table 5, the ratio of percentage of palisade tissue to sponge tissue was larger in the large leaves than in small.

Values recorded in table 6 show the area of internal surface, in square microns, exposed to intercellular space per cubic micron of leaf tissue (volume of cells plus volume of intercellular space). In the large leaves palisade tissue is only 0.96 times as efficient as sponge tissue in exposing cellular surface, while in the small leaves the palisade tissue is 0.97

times as efficient as sponge tissue. Comparison of the mean values in table 6 shows that in both palisade and sponge tissues small leaves have a greater exposure of internal surface per unit volume than large leaves.

Early primary, late primary, secondary, tertiary, and quaternary leaves had an internal palisade surface of 0.156, 0.153, 0.161, 0.162, and 0.169 square microns per cubic micron of palisade tissue, respectively. These same groups of leaves had an internal sponge surface of 0.149, 0.167, 0.171, 0.169, and 0.172 square microns per cubic micron of sponge tissue, respectively.

The mean stomatal density in small leaves was greater than in large leaves (table 7). Early primary, late primary, secondary, tertiary, and quaternary leaves had 215.4, 217.3, 214.0, 266.5, and 312.4 stomata per square millimeter, respectively. Stomata are shown in figures 9, 10, 15, and 16.

The average size of stomatal pores in the large leaves was 8.1 by 2.1 microns, and in the small leaves, 6.7 by 1.6 microns. The average interstomatal distances were 68 microns in the large leaves and 60 microns in the small leaves. (Compare fig. 9 and 10, 15 and 16.)

^a Length and width in microns.

The mean diameters of midrib, lateral veins, and minor veins respectively, are greater in the large leaves than in the small leaves (table 8). Diameters of midribs of early primary, late primary, secondary, tertiary, and quaternary leaves were 145.7, 151.0, 115.9, 99.5, and 101.2 microns, respectively. Diameters of major veins of these groups of leaves were 108.5, 106.5, 84.7, 78.5, and 81.2 microns, while those of minor veins were 32.7, 26.5, 24.0, 21.2, and 20.7 microns, respectively.

Distances between major lateral veins in large leaves averaged 933.1 microns, and in small leaves, 611.0 microns (table 8).

The mean length and mean width of the unit of chlorenchyma (mesophyll) surrounded by minor veins (vein-islet or intervacular interval) was larger in the large leaves than in the small leaves (table 8). Compare vein islets illustrated in figures 13 and 14.

Dimensions (mean length by mean width) of vein islets for the leaf groups were as follows: early pri-

mary, 253×123 microns; late primary, 220×125 microns; secondary, 230×105 microns; tertiary, 168×92 microns; and quaternary, 167×76 microns.

Leaf tissue of large leaves, exclusive of veins, contained a greater mean volume of intercellular space than that of small leaves (table 9). The mean percentage volume of intercellular space was also larger in large leaves than in small (table 9). Calculations based on this table show that the mean volumes of intercellular space in samples from leaves of the different leaf groups, in cubic microns, were as follows: early primary, 240,305; late primary, 197,938; secondary, 153,862; tertiary, 120,937; and quaternary, 98,034. The percentage volumes of intercellular space for these same groups of leaves were 29.4, 26.5, 26.9, 23.2, and 19.9, respectively. Intercellular space in cross sections of leaves is shown in figures 3-7, and in tangential sections, in figures 8, 11-14, 17-20.

DISCUSSION.—*Errors in methods.*—Errors involved in the measurement of internal surface were

^a Dashes indicate data not available.

given by Turrell (1936). They include the maximum error in drawing with the camera lucida, measurement of drawings with chartometer and planimeter, and measurement of the tissues directly with an ocular micrometer. The earlier work was based on single

internal surface and since no data on internal surface were available prior to this study, bias in selection of leaves for internal-surface measurements would be impossible.

From each of the five leaves of plant no. 2, five samples of tissue were chosen at random for every item in the formula used for measuring the internal leaf surface, and were drawn with the camera lucida. These drawings were measured first by the author and then by another investigator. It was thought that a better estimate of error for the method in the hands of various investigators would be obtained by means of measurements made by a second investigator than by means of duplicate measurements made by the author. Duplicate measurements of the internal-external surface ratio in the intervascular interval (R), determined by the two investigators, are given in table 10.

The variance between means of R for the leaves of plant no. 2 is significantly greater than the variance of R within leaves.

A more critical test of the precision of the method of measuring R would be to distinguish between samples chosen at random in the same area of a given leaf rather than between samples from different leaves of the same plant. Snedecor (1934) has outlined a method by which this may be accomplished. While application of his method does not give the error of method of measuring R , it gives an estimate of one of the largest errors in the method, namely, the application of instruments to measuring drawings.

The "within-leaves" comparison contains three of the four variances contained in the "between means-of-leaves" comparison: (1) the variance due to structural variation within the leaf, (2) the variance due to making drawings, and (3) the variance due to measuring the drawing with instruments. Since duplicate drawings were not made of the same samples of leaf tissue, it is not possible to separate structural variation of the tissue from variations in the precision of the drawings; but the degree to which these two ($V.B.$) contributed to the within-leaves variance, as compared with that due to the measurement of drawings ($V.M.$), can be estimated.

$$\begin{aligned} 2 V.B. + 0.36 &= 2.96 \\ V.B. &= 1.30 \\ \frac{V.B.}{V.M.} &= \frac{1.30}{0.36} = 3.61 \end{aligned}$$

This shows that the structural variation along with the small variations in drawing is 3.61 times as large as the variance in the measurements made by the two investigators. This lends confidence to the results obtained by the method of measuring R .

Leaf-growth correlations.—A brief study of the method of growth of alfalfa showed that the number of leaves produced per plant and per node increased with the age of the plant. For instance, a stem with six nodes carried as many primary leaves, while a stem with eight or nine nodes had secondary leaves arising from several of the older nodes having pri-

leaves which were selected to give as near maximum values as possible and yet be comparable between species. The present work on a single species involves the investigation of twenty leaves of various sizes from four plants and random measurements within the central areas of these leaves.

A statistical estimation of the magnitude of some of the sources of error in the measurement of internal surface and of their significance can be made, for instance, on plant no. 2. Since the leaves in this study were selected on the basis of origin rather than of

mary leaves. A plant nearing maturity and having twelve or more nodes bore, at the oldest nodes, tertiary leaves as well as primary and secondary leaves. And a plant having fifteen or more nodes bore many quaternary leaves at the oldest nodes, in addition to the primary, secondary, and tertiary leaves.

First, second, third, or fourth leaves, arising at a given node, or from an axis at a given node, are readily distinguished by the length of their petioles and the size of their leaflets, the latest arrivals having, in general, the shortest petiole and smallest leaflet areas. Thus early primary, late primary, secondary, tertiary, and quaternary leaves at any one node are of decreasing ages. This is reflected clearly in the leaf structure.

Mounts (1932) showed that during leaf maturation the epidermal cells expanded more rapidly than the mesophyll cells and caused the development of intercellular spaces. On this basis, all primary leaves and some secondary leaves may have characteristics of mature leaves (large leaves); while some second-

ary, all tertiary, and all quaternary leaves have characteristics of immature leaves (small leaves) when the plant is near maturity. This is shown by comparison of values in table 11 for large and small leaves. (Though small leaves, having been arrested in growth, have characteristics of immature leaves, they may be quite as mature as the large leaves.) For instance, the ratio of the mean area of upper epidermal cells (ten cells per leaf) of the large leaves (1,446 square microns) to that of the small leaves (1,133 square microns) is 1.28, which shows that the epidermal cells of large leaves expanded 1.28 times in area. A comparison of equal areas in tangential sections of sponge tissue indicates that the area of sponge cells per unit area is only 0.945 as much in large leaves (2,563 square microns) as in small (2,714 square microns). The cellular area per unit area in the epidermis increased, while that in the sponge tissue decreased; thus intercellular spaces were produced. This is illustrated in figures 15-20. These relationships may be more clearly un-

^a Samples of palisade and sponge tissues were measured from tangential sections and were 3,600 square microns in area. Samples of upper epidermis included ten cells each.

derstood by reference to table 12, in which it is shown that large leaves also have, on the average, fewer cells and portions of cells per unit area in adaxial palisade, abaxial palisade, and in the sponge regions than small leaves. (See also fig. 11 and 12, 17-20.)

When data in tables 11 and 12 are rearranged according to the origin of the leaf, the method of intercellular space development is even clearer. In early primary, late primary, secondary, tertiary, and quaternary leaves the total length of exposed cell walls per sample area of 3,600 square microns in tangential sections in the palisade tissue was 561.0, 548.7, 573.7, 582.2, and 607.2 microns, respectively. In the sponge tissue of the same groups of leaves, these values were 372.5, 389.0, 386.7, 395.0, and 419.2 microns, respectively. The mean cellular area per sample area of the sponge tissue for the same grouping of leaves also shows a greater concentration of

cellular material in small leaves than in large leaves.

Obaton (1921) observed that large and small leaves of the same plant genus and of the same age had approximately the same epidermal thickness, palisade thickness, and sponge thickness in each of the six woody genera studied. Large leaves of alfalfa, however, have greater thickness of epidermal, palisade, and sponge tissue than small leaves. Reference to the data in table 4 shows that this is the case. The differences in structure are clearly evident in figures 3-7.

The greater internal surface of large, mature alfalfa leaves apparently is not due to greater efficiency of palisade tissue in exposing surface, since palisade tissue is less efficient than sponge tissue in this respect (table 6).³ But the greater actual thick-

³ In woody species, Turrell (1936) found a higher efficiency of exposure in palisade tissue than in sponge tissue.

^a "See Turrell (1936)."

^b These leaf groups were given arbitrary values as follows: primary (early and late), 1; secondary, 2; tertiary, 3; quaternary, 4 (see text, page 412).

ness of palisade and sponge tissues in large leaves accounts largely for the greater internal surface of these leaves (table 4). The effect of the thickening of the lamina in large leaves on the internal exposed surface is offset somewhat by the smaller amount of cell-wall perimeter and cellular area in samples of the tangential leaf sections (cell-wall perimeters and cellular areas have a small negative correlation with leaf area [table 13]).

The coefficient of correlation between internal-external surface ratio (*R*) and leaf thickness (table 13) is high and highly significant.⁴ The relationship is expressed by the regression equation (table 14), the standard error of estimate of which is 1.0, where *T* is leaf thickness, expressed in microns, and *R* is the internal-external surface ratio.

For leaves of alfalfa grown under the same conditions, the best linear relationship between leaf thick-

ness and leaf area is represented (fig. 21) by the regression equation (table 14), *T* representing leaf thickness in microns and *A*, leaf area in square centimeters. The standard error of estimate is 33.4 microns (table 14).

Leaf area is moderately and highly significantly correlated with *R*, as shown by the correlation coefficient (table 13). This relationship is more clearly seen in the regression line (fig. 22), the equation for which is shown in table 14, *R* representing internal-external surface ratio and *A* the area of the leaf, in square centimeters.

In table 13 the degree of correlation between estimated leaf area,⁵ mesophyll thickness, leaf thickness and various tissue thicknesses, tissue measurements, and internal-external surface ratios are also given. The probability of the chance occurrence of the correlation coefficient found is indicated as one chance

⁴ For significance of correlation coefficient see Fisher (1932).

⁵ Leaf area was not determined with planimeter for these calculations.

in one hundred ($P=0.01$), two chances in one hundred ($P=0.02$), five chances in one hundred ($P=0.05$), and ten chances in one hundred ($P=0.10$). That the correlation coefficients of estimated leaf area and other items approximate the correlation coefficients of measured leaf area and other items is shown by comparison of r for estimated leaf area and R , and r for planimeter-meas-

Fig. 21. The regression line of leaf thickness (T) on leaf area (A), where T is expressed in microns and A , in square centimeters.

TABLE 14. Regression equations and standard errors of estimate of certain measured items of alfalfa leaves.

R on leaf thickness. .	$R = 3.97 + 0.04T$	1.0

^a T = leaf thickness in microns; A = leaf area in square centimeters.

ured leaf area and R (table 13): the former is $+0.61$ and is highly significant; the latter is $+0.50$ and is significant.

As shown in table 13, estimated leaf area is positively and moderately correlated with upper and lower epidermal thickness, palisade thickness, leaf thickness, major-vein diameter, minor-vein diameter, R , R_{va} , and R_{vi} , as indicated by the correlation coefficients, which range around $+0.5$. It is negatively correlated with the origin of the leaf in relation to the main stem. When primary leaves are arbitrarily given a value of 1; secondary leaves, 2; tertiary leaves, 3; and quaternary leaves, 4 (table 13), the correlation coefficient is -0.8 . Mesophyll thickness and R were highly and significantly correlated in three of the plants. Mesophyll thickness and R were highly but not significantly correlated in early primary, late primary, and secondary leaves; the correlation was high but not significant for tertiary and quaternary leaves. The correlation was high between mesophyll thickness and R , R_{va} , or R_{vi} , and

the correlation coefficient was highly significant. Leaf thickness and R were highly but not significantly correlated in early primary, late primary, and secondary leaves; they were moderately but not significantly correlated in tertiary and quaternary leaves. When the entire sample was considered, however, the correlation was very high and highly significant between mesophyll thickness and R , and leaf thickness and R .

The latter two correlations suggest that when a population of leaves from this variety of alfalfa is sampled, such complicated estimates as R might be made from a regression equation based on leaf area when high accuracy is not essential and based on mesophyll thickness when high accuracy is desirable.

The relation of plant maturity to SO_2 injury.—Because of the mode of growth of the alfalfa plant some relation between maturity and sulphur dioxide injury might be expected, for early in the develop-

Fig. 22. The regression line of internal-external surface ratio (R) on leaf area (A), where the latter is expressed in square centimeters.

ment of the plant several primary leaves are formed; later, secondary leaves arise; increasing numbers of both are produced before tertiary leaves appear. Finally, still accompanied by production and maturation of leaf types already named, the quaternary leaves arise. Since large leaves, that is, early primary, late primary, and some secondary leaves, are readily injured, while small leaves, that is, some secondary, tertiary and quaternary are not so readily injured, it might be expected that the total leaf injury to a mature plant would always be greater than that to an immature one under the same conditions, because of the large number of large mature leaves; but the percentage injury might not necessarily always be expected to be much greater, since the quantity of small immature leaves which are not readily injured affect the percentage. Nevertheless, if the plants are selected in the correct growth stages, the percentages are also affected, as indicated by cal-

culations based on Hill's and Thomas' curves (1933) for the percentage leaf area destroyed in early growth (25 per cent to 40 per cent growing time), in medium growth (40 per cent to 60 per cent growing time), and in late growth stages which give the relative amount of leaf injury as 16.9, 23.5, and 33.6, respectively. The injury at maturity is 33.6/16.9, or 1.99 times the injury at early growth stages.

The relation of leaf structure to SO₂ injury.—The effect of maturity in sulphur dioxide injury has been based on the size of leaves, and since the size of leaves has been shown to be closely related to a number of morphological features of the leaf, these might well be examined with respect to leaf injury by sulphur dioxide gas.

Measurements show that both the upper and lower epidermis of large leaves are thicker than those of small leaves (table 4). The differences in these features may be seen in figures 3 to 7. Since large leaves show injury first, epidermal thickness and cuticle thickness, therefore, are not positively but negatively correlated with SO₂ injury, when considered barriers to SO₂ absorption.

Entrance to the intercellular space of alfalfa leaves is provided by stomata on both surfaces of the leaf and this suggests an arrangement for more rapid gaseous exchange between intercellular space and external atmosphere than in leaves having stomata only on one surface. This stomatal situation in conjunction with the very thin cell walls (fig. 8, 11 and 12) of the mesophyll, may in part explain the sensitivity of alfalfa to SO₂, as noted by Setterstrom, Zimmerman, and Crocker (1938); while the variability in the exposure of cell wall may explain why injury to the leaf occurs in spots.

In large alfalfa leaves we have shown that 27.5 per cent of the leaf sample volume was intercellular space, while in small leaves only 22.9 per cent was intercellular space. If some environmental condition caused closure of stomata during fumigation with SO₂ shortly after the gas in the intercellular space is in equilibrium with that in the external air, then large leaves would accumulate 4.6 per cent more SO₂ per unit sample volume of leaf tissue than small leaves. Since the average large leaf contains about 0.0109 cc. of intercellular space in the entire leaf, and the average small leaf contains 0.00184 cc., under the same conditions stomatal closure would cause large leaves to trap about 5.9 times more SO₂ than small leaves.

Brown and Escombe (1900) showed that the distribution of small apertures which most efficiently transmitted gases through thin membranes was where interaperture distances were about ten times the aperture diameters, in cases where there was no air movement. In large alfalfa leaves the mean interstomatal distance calculated from the stomatal density data is 68 microns and is significantly different from 60 microns for small leaves. By making further calculations according to Sayre's modification (1926) of Brown and Escombe's law, we find the diameter of a circular pore with a perimeter equal

to that of the average of elliptical stomatal pores in large leaves would be 5.9 microns, while in small leaves it would be 4.8 microns. Thus large leaves which are more readily injured by SO₂ have a more efficient distribution of stomata for transmission of gas in still air. See figures 9, 10, 15, and 16.

In moving air Brown and Escombe showed that diffusion of gas through thin membranes was proportional to the pore area. In the field where there is nearly always some air movement the significantly larger stomatal pore areas of large leaves would favor transmission of SO₂ with attending greater injury.

Thomas and Hill (1937) have noted a translocation of sulphur from fumigated leaves. Our measurements show large leaves had larger mean vein diameters in the midribs, lateral veins, and in the minor veins, respectively, than small leaves (table 8). The larger leaves thus may be better adapted for translocation than small leaves, and on this basis they would be expected to show less injury though perhaps greater absorption coefficients because of removal of products formed with SO₂. However, the protoplasm is apparently injured in the large leaves before the toxic mixture reaches the veins, so that a negative correlation exists between vein diameter and SO₂ injury.

A partial explanation of the negative correlation between vein size and sulphur dioxide absorption and injury probably lies in the greater distances which the sulphur complex must be transported before reaching the specialized conductive tracts in large leaves. Both the lengths and widths of the vein islets (mesophyll units) are larger in large leaves than in small (table 8), so that a positive correlation exists between the distance that the SO₂ must be transported to reach the veins and the degree of injury. This is probably in some way related to the internal exposed surface and will be discussed later. Difference in vein islet size is illustrated in figures 13 and 14.

As shown by analyses of variance, the large leaves were significantly greater than small leaves in the area of internal surface (R) in the intervacular interval exposed to intercellular space per unit leaf surface (7,200 square microns). And it has been noted by Hill and Thomas (1933) that the large alfalfa leaves are injured more readily and more severely than small ones. They (Thomas and Hill, 1937) have also shown that the large leaves (primary and secondary) of Utah Common Alfalfa contained approximately 2 per cent sulphur after twenty-two days of continuous fumigation with sulphur dioxide (concentration of 0.24 ppm.), while the small leaves (tertiary) contained 1.3 per cent or approximately the normal percentage of the dry weight for unfumigated leaves. A positive correlation, therefore, exists between large leaf size, high internal-external surface ratios, large sulphur dioxide absorption, and high degree of leaf injury.

An analysis of variance shows that the difference between the internal surface ratio in the intervacular

cular interval and in the region of the major lateral veins is significant. Hill and Thomas (1933) noted that not even large leaves were injured near the veins. This observation correlates positively with the significant reduction in the internal exposed surface along the major veins of large leaves.

Fig. 23. The percentage sulphur found in primary, secondary, and tertiary leaves by Thomas and Hill (1937) plotted against the internal-external surface ratios (R) of primary ($R=14.52$), secondary ($R=10.94$), and tertiary ($R=10.34$) leaves. The concentration of SO_2 to which the leaves were subjected was 0.175, 0.175, and 0.2–0.3 ppm. in curves I, II, and III respectively. Note that the curves indicate that in this low concentration of gas the internal surface limits absorption of the gas principally in the tertiary leaves.

It is possible, however, that all the cellular material (mesophyll) in the vein islet acts as a unit, since translocation of absorbed and oxidized toxic gas from the mesophyll will depend upon the minor vein which surrounds it. The area of the vein islet in large leaves is significantly larger than that in small leaves, as calculated by the method of analysis of variance. In the average large leaf the mean internal-exposed surface of the mesophyll is 763,979 square microns in the average vein islet. For the average small leaf vein islet the mean internal exposed surface of the mesophyll is 382,406 square microns. The average cellular volume in the intervacular interval of large leaves is 3,213,000 cubic microns, and in small leaves the average cellular volume in the intervacular interval is 1,383,000 cubic microns. In the large leaves the ratio of the internal exposed surface for the intervacular interval to the volume of mesophyll cellular material is 0.238; in small leaves it is 0.240. Since these ratios are not significantly different, the ratio of the internal-exposed surface per vein islet, and the minor vein absorbing area or minor vein volume must be the effectual unit. The former in large leaves is 23.7, in small leaves, 18.7; while the latter is 3.22 for large leaves and 3.60 for small leaves. Clearly, if among other factors morphological factors affect absorption and

injury by SO_2 , the important factor must be the ratio of internal exposed surface of the vein islet and the area of the minor vein absorbing surface surrounding the islet.

The positive correlation of the internal-external exposed surface ratio with SO_2 absorption is shown in figure 23, in which analysis of primary, secondary, and tertiary leaves for sulphur by Thomas and Hill (1937) has been plotted against our measurements of internal surface ratios of primary, secondary, and tertiary leaves.

Thomas and Hill (1935) have shown the absorption value of sulphur dioxide by alfalfa, x , to be equal to tAC , where t equals time of fumigation (duration), C equals concentration of sulphur dioxide in the air, and A equals an absorption factor which is a measure of the activity of the plant. The value of A was determined under various conditions of light intensity, relative humidity, sulphur dioxide concentration, time of exposure, maturity of plants, succession of crops, seasons, and years (1928–1931). The ratio of the maximum absorption factor to the minimum is 21.6, while that of the largest internal-external surface ratio per sample area to the smallest is 2.08, and the ratio of the internal exposed surface per unit of minor vein area for large/small leaves is only 1.26. The ratio for the absorption factor is nearly ten times that for the internal-external surface ratio and over seventeen times the internal exposed surface per unit minor vein area for large and small leaves. The wide variation in the absorption coefficient A as compared with the variation in the internal-external surface ratio calculated to any base, shows that other factors in aggregate have a much greater effect on sulphur dioxide absorption under the large variety of conditions in which fumigations have been made. Wells (1917), for instance, has pointed out that plants are five to six times as resistant at night and suggests this is due to closure of the stomata. Conditions which would affect closure during the day might likewise make large increases in the resistance to SO_2 .

SUMMARY

Measurements of alfalfa leaves showed that areas of late primary, early primary, secondary, tertiary, and quaternary leaves were, on the average, successively smaller. The leaf thickness, upper and lower epidermal thicknesses, palisade and sponge thicknesses, midrib, major-vein, and minor-vein diameters were, in general, greater in the primary leaves and successively smaller in secondary, tertiary, and quaternary leaves. When the leaves were divided into two classes, large (those larger than 1 centimeter in area) and small (those smaller than 1 centimeter in area), the large leaves were found to have greater mean leaf thickness, upper and lower epidermal thickness, palisade and sponge thickness, and greater mean midrib, major-vein, and minor-vein diameters.

The internal-external surface ratios calculated for the intervacular interval, for the region of the major veins, and for the region of the minor veins were successively smaller for early primary, late primary, secondary, tertiary, and quaternary leaves. For any one of these classes of leaves, the internal-external surface ratio was largest in the intervacular interval, intermediate in the region of the minor veins, and smallest in the region of the major veins. When the leaves were grouped as large and small, the internal-external surface ratio was larger in the large leaves.

Volume of intercellular space was largest in early primary leaves, successively smaller in late primary, secondary, and tertiary leaves, and smallest in quaternary leaves. When the leaves were grouped as large and small, the large leaves had the greater volume of intercellular space.

The length and width of vein islets and of epidermal cells were greater in large leaves than in small leaves.

Stomatal density was lower in large leaves than in small leaves, but the stomatal pores were larger in the large leaves.

Leaf area was positively, moderately, and significantly correlated with epidermal, palisade, and leaf thickness, with major- and minor-vein diameter, and with internal-external surface ratio; the correlation coefficient was approximately $+0.5$. Leaf area was negatively, moderately, and significantly correlated with sponge-cell area (determined in tangential section), and the correlation coefficient was approximately -0.5 . Mesophyll thickness and internal-external surface ratio were positively, highly, and significantly correlated; and the correlation coefficient was $+0.9$, which suggests the possibility of using mesophyll thickness in estimating internal-external surface ratios from regression equations.

Large internal-external surface ratios, large volumes of intercellular space, large stomatal pores and large vein islet areas are positively correlated with large leaf size and reported greater SO_2 injury in large leaves.

SHRINKAGE AND CELL WALL STRUCTURE OF COTTON FIBERS¹

Earl E. Berkley

THE SHRINKAGE of natural fibers such as cotton, is dependent upon the fine structure of the fiber and its physical condition. The structure, as variously described in the literature, is still debatable but the physical condition of the fibers can be controlled within reasonable limits. A study of the shrinkage resulting from a reduction in moisture content may aid in the determination of the fundamental structure of the fiber.

The microscopic structure of the cotton fiber has been described by Balls (1923), Denham (1923), Anderson and Kerr (1938), Hock, Ramsay and Harris (1941), and others. The fine structure as determined by x-ray diffraction has been described by Berkley (1939). Certain phases of the literature dealing with cellulose and cell wall structure in general have been reviewed recently by Bailey (1938, 1939), Kratky (1940), Mark (1940) and Nickerson (1940), and the need for studies in cotton fiber character were discussed by Conrad and Webb (1935), so no extensive review will be attempted here.

Briefly, the cotton fiber is a single cell and contains a primary wall and a secondary thickening as described by Kerr and Bailey (1934) for other plant fibers. The primary wall is the first formed layer and constitutes the thin sheath, approximately $0.5\ \mu$ in thickness, on the outer surface of the mature cotton fiber. The crystalline cellulose is arranged at an angle of 70 to 80 degrees to the fiber axis (Balls, 1923; Anderson and Kerr, 1938).

The secondary wall is laid down on the inside of the primary wall next to the lumen. The crystalline cellulose of the secondary thickening lies in a spiral in the fiber, direction of which changes frequently from an S to a Z spiral, or vice versa. According to Anderson and Kerr (1938), the direction of the spiral of the first layer is usually opposite that of the succeeding layers, all of which follow in general a given pattern. The pitch of the spiral, that is, the angle between the long axis of the fibrils and that of the fiber, varies with the variety of cotton and the climatic condition under which it is grown (Berkley, 1941; Kerr, 1941; Barre and Berkley, 1942).

The samples used in these studies varied in age from ten to thirty days after bloom and represent either the primary wall only, or both the primary and the secondary walls as indicated.

The shrinkage of "green" moist cotton fibers as a result of drying has received little attention in connection with the studies of quality of raw cotton and

other natural fibers. Collins (1930) discussed the swelling and shrinkage of air-dry mercerized cotton with changes in moisture content, but the results of his studies on modified cellulosic fibers are not comparable with those reported in this paper.

The term "shrinkage" as used here is intended to mean the contraction in length, breadth or volume of the cotton fiber, whereas the term "swelling" is used to indicate the expansion of the fiber in any one of these dimensions. The data are confined principally to the longitudinal shrinkage. By green condition is meant the wet fibers taken, without drying, from the bolls and kept thereafter, until used, in liquid preservatives.

MATERIALS AND METHODS.—Seven varieties representing two species of cotton, *Gossypium hirsutum* L. and *G. barbadense* L. were used in these studies. The samples were collected at Raleigh, North Carolina,² during the summers of 1937, 1939 and 1940. Flowers were tagged in the field and the samples collected at the desired ages. The young bolls, ten to thirty days old, were brought into the laboratory, opened immediately and the locks dropped into boiling water where they were allowed to remain for five to ten minutes. A number of measurements were made on fibers with no further treatment but the majority of the samples were preserved in sufficient 95 per cent alcohol to give approximately 70 per cent alcohol when combined with the water in the tissue.

The fibers on a given seed were paralleled by the method described by Berkley (1939) for the preparation of x-ray samples. This treatment consisted of combing the fibers under a stream of running water without removing them from the seed. A dissecting needle, passed through the seed and used to hold it while combing the fiber, was then stuck into one of two boards tacked together.³ It was inserted at such a height on the vertical board that the tips of the fibers matted on a small piece of soft filter paper placed on the board below. The fibers were permitted to drain until they settled around the seed and formed a relatively dense bundle. The distance between the bottom of the seed and the filter paper was then measured with a pair of dividers and a steel ruler graduated in hundredths of an inch. These bundles were then permitted to dry over night at room temperature. The distance between the bottom of the seed and the filter paper was again measured. From these two measurements the air-dry longitudinal shrinkage was calculated. A number of other

² Certain of the series of samples were collected and preserved by Dr. Thomas Kerr, Cytologist, Bureau of Plant Industry and North Carolina State Experiment Station and his staff at the North Carolina State College, Raleigh, North Carolina.

³ Two soft pine boards about three inches wide and four feet long were tacked together along the edges to form a trough or V. One board when lying on the table served as a base, the other stood vertical. The needles were placed in the vertical board.

¹ Received for publication October 20, 1941.
Presented before a meeting of the Cellulose Division, American Chemical Society, St. Louis, Missouri, April 7-11, 1941.

The author wishes to express his appreciation to Carl M. Conrad and Robert W. Webb of the Agricultural Marketing Administration, and to Thomas Kerr of the Bureau of Plant Industry for helpful suggestions during the progress of the work and the preparation of this manuscript.

methods of preparation and measurement of the bundles were tried with less success.

The fibers which had coalesced into a hard, rigid bundle were then cut as near the seed and the filter paper as possible and remeasured. Half of the bundles were placed in water and allowed to soak over night. The other half were placed in a drying oven at about 105°C. and allowed to dry for about four hours, after which the oven-dry length was determined. The next day when the bundles from the water were measured, those from the oven were placed in water to soak over night and those from the water were oven-dried. In this way it was possible to measure the regain in length from both the air-dry and oven-dry condition to the water-wet condition.

CHEMICAL TREATMENTS.—The chemical treatments described here are in addition to the boiling water and preserving solution previously mentioned. A small number of samples were extracted with 95 per cent ethyl alcohol for about four hours to remove the waxes. A portion of these was measured for shrinkage without further treatment. Another portion was further treated to remove the pectic substance and then measured for shrinkage. Three methods were used to remove the pectic substance: first, by treating over night in 96 per cent acetic acid,

Fig. 1. Per cent shrinkage and elongation of cotton fibers representing various ages for seven different varieties of cotton. The recovery (broken line), is the percentage of the green length that the fiber elongated, after it was dried to the air-dry condition. For the most part the recovery was parallel with and amounted to more than 50 per cent of the shrinkage (solid line). Note the wide differences in slope and the position where the first break occurs in each series. The position of the break indicates the age at which secondary thickening was initiated in the fibers. Each plotted point represents the average of ten or more bundles.

washing and treating over night again in 2 per cent ammonia, according to the method described by Whistler, Martin and Harris (1940); second, by treating for several hours at 80° to 90°C. in ammonium oxalate or, third, by boiling for one hour or more in 1 per cent sodium hydroxide solution.

Approximately 50 per cent of the loss in length resulting from the removal of water by drying was

non-reversible when the fibers were submerged in water after drying. Caustic of mercerizing strength and cuprammonium solutions were used to swell the fiber further and to determine, if possible, the type of structure associated with this phenomenon in the primary walls of the cotton fiber.

Fig. 2. Per cent shrinkage of cotton fibers of various ages after different treatments: upper charts show shrinkage after boiling in water (smooth lines) and after additional extraction with 95 per cent alcohol (broken line); lower chart shows shrinkage from alcohol preservation after air-drying (smooth line) and after additional oven-drying (broken line). Each plotted point represents an average of ten or more bundles.

Previously dried samples were swollen in water and then in 18 per cent sodium hydroxide or cuprammonium hydroxide solution⁴ and the percentage of elongation upon swelling was measured. As many as ten alternations of the swelling reagent and water were used on certain samples.

The treatments with 18 per cent sodium hydroxide were carried out at room temperature, at 80°C., and in an ice bath, or refrigerator. In all cases the caustic was washed out with distilled water at room temperature.

Difficulties in paralleling fibers.—Cotton fibers fold back and forth in the process of elongation in the growing boll and thus become kinky. In the early stages before secondary thickening appears, the fibers are very fragile. They tend to adhere to each other and break rather than straighten out when combed under a stream of running water. If they are first boiled in water for a few minutes the kinks gradually disappear and the surface of the fibers becomes slimy or gelatinous so that they may be paralleled with little difficulty.

⁴ Containing 30±0.2 g. copper and 165±1.0 g. ammonia per liter.

RESULTS.—*Shrinkage*.—When the fibers from ten-day-old cotton bolls were boiled in water, combed parallel and dried, they lost from 30 to 50 per cent of their original length (see fig. 1). During the following days, the lengthening fibers from successively older bolls showed gradually decreased shrinkage, up to the stage of secondary wall formation. When secondary thickening began, shrinkage rapidly fell

Fig. 3. The effects on cotton fiber length of 18 per cent sodium hydroxide at different temperatures. The solid lines represent the data for 18-day-old fibers and the broken lines, 25-day-old fibers.

off for a period of from two to five days, depending on the variety of cotton and weather conditions, after which only slight changes were observed.

This trend appears to be generally characteristic of the varieties of cotton studied, but the rate of change in the shrinkage during the period of elongation of the fibers varied appreciably. Figure 1 includes one series (Mexican Big Boll, 1939) in which the shrinkage showed little progressive change between the 13th and the 18th day after the flowers opened. On the 19th day, secondary wall was being laid down and the per cent shrinkage decreased appreciably, after which it continued to fall off more or less rapidly until the 22nd day.

During the primary wall stage, treatments such as extraction in hot 95 per cent ethyl alcohol to remove the waxes of the fiber increased the longitudinal shrinkage on the average about 4 per cent, as seen in figure 2. Further treatments to remove the pectic substances, such as with hot 0.5 per cent ammonium oxalate and 96 per cent acetic acid followed by 2 per cent ammonia, increased the shrinkage about 7 per cent more.

The fiber appears to become slimy on the surface during the boiling water treatment. It is difficult to determine what the boiling water does to the structure, since there are three systems: a wax, a pectin, and a cellulose system. The effect may be due to a disintegration of the pectic substances of the cotton fiber. If so, it is quite possible that an increased shrinkage of the fiber may be expected from this treatment.

In figure 2, the difference between the shrinkage when the bundles were dried to the air-dry, and subsequently to the oven-dry, condition may also be seen. Similar differences were observed in all series studied, but in order to save space the data have been omitted from this manuscript. The permanent or non-reversible shrinkage, as shown in figure 1, was also increased when the fibers were oven-dried. The air-dry fibers usually regained 50 per cent or more of their loss in length upon re-wetting in water, whereas the oven-dry samples regained a smaller percentage of their loss.

The ends of green cotton fibers, which contain primary wall only, were fastened and the cotton was allowed to dry. The fibers shrank in length as usual and in so doing the bundle ruptured. Before rupture occurred, there appeared to be a certain amount of flow in the cell wall substance, presumably in the amorphous portion, as shown by the drawing of the fiber bundle to a much smaller diameter. It is recognized that a certain percentage of the fibers could have ruptured during this process, thus reducing the diameter of the bundle, but no evidence of this was found.

Elongation due to swelling.—A certain percentage of the loss in length is recovered when green cotton fibers which have been previously dried are soaked in water. During the primary wall stage, 50 per cent or more of the air-dry shrinkage is reversible, as shown in figure 1, but after the secondary wall is formed this figure is greatly reduced. If the fiber bundles are dried to the oven-dry condition less than half of the loss at any stage is regained by subsequent soaking in water.

Previously dried bundles of cotton fiber which contained primary wall only increased in length, whereas those which contained secondary thickening decreased in length when submerged in 18 per cent sodium hydroxide, irrespective of temperature (fig. 3). The rate of change was increased by an increase in the temperature of the caustic. At 0 to 3°C., swelling reached a maximum in approximately one hour, although there were slight increases in certain samples upon prolonged treatment. At room temperature, the period required for the swelling to reach a maximum varied somewhat from sample to sample, but in general there was little increase after about twenty minutes (fig. 3). At 80°C. the increase of length of fibers containing primary walls only was very rapid but short lived. It was difficult to determine the extent of elongation as the fibers began to shrink in length within the first five minutes in the hot caustic. The bundles were rapidly dissolved so

that only a small residue in the form of a fine thread remained after about twenty minutes. Examination of the fibers under the microscope showed a reduction both in length and diameter. The samples with primary wall only, when treated at room temperature, began to decrease in length after about twenty-four hours, whereas those treated at 0° to 3° showed no signs of longitudinal contraction at the end of six weeks' treatment.

When bundles of fibers containing primary walls only were treated alternately in 18 per cent sodium hydroxide and water, the length changed rapidly. At 0° to 3°C. the bundles increased in length when washed in water but, when retreated with the caustic, they came back to approximately the same length they had assumed before. Water at room temperature was used in all cases regardless of the temperature of the caustic. There was little tendency for shrinkage in the samples treated in the cold caustic, but those treated at room temperature and particularly those treated at 80°C. showed a rapid decrease

Fig. 4. The effects on cotton fiber lengths of alternate treatments with water and 18 per cent sodium hydroxide at different temperatures. The solid lines represent the data from the 18-day-old fibers; the broken lines, that from the 20- and 25-day-old fibers.

in length when washed in water. After the first two or three alternations, the bundles retained their length or increased slightly in the caustic but shrank appreciably in the water (fig. 4). Since the increase

of length in the caustic did not equal the decrease in length in the water, the bundles gradually lost up to 50 per cent or more of their lengths. Further treatments, no doubt, would have continued this reduction.

The bundles which contained secondary thickening showed a progressive change in length with alternate treatments of caustic and water at 0° to 3°C. and at room temperature but no tendency to shrink more rapidly in the water than in the caustic (fig. 4).

Fig. 5. The effects of cuprammonium hydroxide solution on the length of cotton fibers which had previously been dried. The solid line represents the data for 16-day-old fibers; the broken line for the 25-day-old fibers.

When bundles of dry fibers containing only primary walls were treated with a cuprammonium solution, they increased rapidly in length. The gain in length, as shown in figure 5, was from 0.52 to 0.81 inch, or approximately 56 per cent of its dry length, but in no case did the bundle swell to its original green or preserved length. On the other hand, a bundle of the fibers which contained secondary thickening shrank from 0.94 to 0.70 inch, about 26 per cent, in length before it became a jelly-like mass and dissolved. Those containing only primary walls remained intact until after they had been washed in water and treated again in cuprammonium hydroxide solution.

DISCUSSION.—It has been repeatedly demonstrated by the use of x-ray technique that the dimensions of the unit cell of the cellulose crystal do not change with changes of moisture content in the fiber. It is not likely, therefore, that the dimensions of the crystal will change under the same conditions. If this is true, the shrinkage of green cotton fibers, upon drying, must take place in the layers between the crystals. It remains only to demonstrate, then, whether the areas from which the water is removed are simply crystal faults or cracks between the crystals or whether they are areas of amorphous materials which, with the water, form a jell and serve as an adhesive material that binds the crystals together.

The water may wet the entire surface of a crystal and an individual molecule that does not form a part of the crystal lattice. Such molecules when existing in the amorphous state may be bound to other molecules or crystals at certain points but the major part of the long chain is wound in and out at random among the other molecules. The water covering its surface increases the volume of the mass, but the changes in volume with changes in moisture content are controlled more by the shape and size of the area of amorphous structure than by that of the molecules.

Kratky (1940) suggested that the enormous strength of cellulosic fibers could hardly be accounted for, unless there was some structure in the areas absorbing the water. This is especially true, since the dimensions of certain cotton fibers used by Collins (1930) in his studies changed as much as 48.6 per cent going from water-wet to zero per cent relative humidity on the basis of the area at zero per cent relative humidity. A layer of water thick enough to give the changes in area of mature fibers observed by Collins (1930) would undoubtedly weaken the fibers materially. It may be well to remember in this connection that the tensile strength of cotton fibers is usually increased with an increase in moisture content, rather than reduced. This can be explained on the basis of the presence of a somewhat plastic adhesive substance, such as an amorphous structure surrounding the crystals but it does not support the assumption that there are only cracks into which the moisture enters.

There has been considerable discussion in the literature concerning the size and shape of the crystallites or individual units of the cellulose crystal. Only a few of the suggestions will be mentioned here. Nägeli (1864) concluded, on the basis of the physical properties of cellulose, that the crystals or "micelles" were of sub-microscopic dimensions, and that water penetrated between them to cause swelling. Ritter (1935) observed needle-like strands which he termed "fusiform bodies," and Hock and Seifriz (1940) and Wergin (1938) stated that the fibrils could be broken down into smaller units.

Farr and Eckerson (1934) suggested that the cellulose was discontinuous in the form of ellipsoidal particles, each covered with a thin layer of pectic substance. The presence of such particles has not been confirmed and the existence of a pectic adhesive material surrounding the cellulose has been thoroughly disproved as shown by the work of Whistler, Martin, and Harris (1940), Howells (1941) and Heuser and Green (1941).

Bailey and Kerr (1935, 1937) suggested that, in the case of wood, both the cellulose and non-cellulose systems were continuous in the form of a net-like structure and that the units graded down to the limits of microscopic visibility. This theory was further amplified by Bailey (1938, 1939) and by Frey-Wyssling (1936, 1937, 1938a, 1938b).

Kratky and Mark (1937) working on regenerated cellulose, suggested that, instead of having discrete crystalline units, a given cellulose molecule may ex-

tend through a large number of crystals with the intermittent segments existing in the amorphous state.

The writer has been able to macerate in cuprammonium solution and phosphoric acid cotton fiber cell walls into fine needle-shaped units which grade down to the limits of microscopic visibility. Long slender lines which appear to be the light diffracted from small units which cannot be resolved can be seen as they separate from the cell and float away in the macerating fluids.

At present the best hypothesis appears to be that the cellulose crystals may or may not be sub-microscopic in size. They undoubtedly reach a length as great as that of the cellulose molecule which is thought to be as much as 1 to $1\frac{1}{2}\mu$ long, and they are surrounded by an amorphous matrix which, in the case of the secondary wall of the cotton fiber, at least, appears to be cellulose itself. The non-cellulose constituents of the primary wall, such as, for example, the waxes and the pectic substances, may or may not be crystalline, but they too are dispersed in this amorphous matrix and each may, in turn, exist as a continuous system.

Hock and Harris (1940) found that the pectic material of the primary wall of the cotton fiber formed a continuous membrane after they treated the fiber to remove all the cellulose. It has also been demonstrated that treatments to remove the pectic substances and the waxes do not reduce the tensile strength of cotton; therefore, the cellulose must be continuous. According to these interpretations it would appear that Farr and Eckerson (1934) were correct in their assumption that particles of cellulose were surrounded by an isotropic matrix, but they were apparently mistaken about the size and shape of the particles and the chemical nature of the adhesive substance.

In summarizing, the cellulose of the cotton fiber may be considered as existing both in the crystalline and the non-crystalline states as illustrated in figure 6. The crystals, like the fiber, are apparently many times longer than broad and may or may not be aggregated into bundles such as fibrils. The amorphous substance between these fine crystals is largely cellulose, and it contains an enormous quantity of water in the native green state, much of which is permanently lost upon the drying of the fiber. As the water disappears, the amorphous structure shrinks. Since the crystals are not all parallel, they may bridge to prevent the units from coming together and the amorphous structure ruptures to form air spaces in the tissue. These air spaces are probably irregular in shape and position, but it is indicated that they may be more numerous in certain areas of the fiber than in others. For example, the rapid swelling of the less dense portion of the daily growth ring of the cotton fiber, in contrast to the denser portion, as shown by Kerr (1937), may be due to its porous nature which permits the rapid penetration of the swelling agent.

With this picture in mind (see fig. 6) there are two possible explanations for the changes in shrinkage

Fig. 6. A diagrammatic sketch of the fine structure of cellulose in cotton fibers. The parallel lines are intended to represent the crystalline and the wavy lines, the amorphous cellulose. Each group of parallel lines make up a crystallite, and each group of crystallites may be considered as representing a fibril.

of the primary wall of the cotton fiber with increasing age:

First, the orientation of the cellulose in relation to the major fiber axis has been observed by Anderson and Kerr (1938) to vary as the fiber elongates. Hock and Harris (1940) further observed that this variation was progressive and that the cellulose in the tip of the fiber was more nearly perpendicular with the fiber axis than that at the base.

Second, Anderson and Kerr (1938) have observed that the birefringence of the primary wall of the cotton fiber also increases with increased age. This may be due either to an increase in the degree of crystallization of the cellulose already present in the fiber wall or to the deposition of additional crystalline cellulose after the wall is formed. Another possibility is that there is more crystalline cellulose deposited in each of the successive portions of the wall as the fiber elongates.

Further evidence of the presence of an amorphous layer between the crystals is suggested from the permanent loss of length upon drying. Approximately 50 per cent of the loss in length of the young fibers, which contain primary walls only, is permanently

lost upon drying. This represents about one-fifth of the total length of the fiber. This loss could be accounted for on the assumption that the crystals are discrete and are separated only by cracks or faults, and that bonds form between certain of the crystals and thus prevent the re-entrance of the water. In such a case, it is difficult to understand why the swelling agents used in these studies, such as cuprammonium solution or 18 per cent sodium hydroxide, would not sever these bonds and permit the fiber to swell back to its original length. This does not take place as shown by the data, and the nature of the swelling observed would indicate that the presence of an amorphous structure between the crystal units is more likely.

It is easier to visualize that bonds form between individual cellulose molecules in the amorphous regions, thus preventing the full amount of swelling that would otherwise have taken place in the water, and, since the molecules are already dispersed to a certain degree, they would probably go into solution rather than swell appreciably in the cuprammonium solution and the mercerizing caustic.

The major portion of the primary wall of the cotton fiber appears to be made up principally of amorphous materials with crystalline cellulose and waxes dispersed more or less widely in them. So far as can be determined the pectic compounds and the waxes are largely confined to the primary wall. There may be some pectin on the surface of the lumen and some waxy material in the protoplasmic residues. The amorphous phase of the secondary thickening is less extensive than in the primary wall and appears to be composed of cellulose. The slight longitudinal shrinkage observed in the secondary thickening can be accounted for on the assumption that the cellulose crystals are many times longer than broad. They overlap in such a way that there is practically no shrinkage along their major axes. The shrinkage that is observed along the fiber axis is apparently that expected from the component of the lateral shrinkage due to the spiral of the cellulose in the fiber.

The loss of length of the fibers with primary wall only, in the mercerizing caustic at room temperature and above, needs further study before reliable conclusions can be drawn. It would appear from the shrinkage that the cell wall substance is highly soluble in the caustic. The soluble portion is probably the amorphous material. It has also been found that the crystalline phase of the cellulose shows up much better after an extraction in alkali and a wax solvent (Sisson, 1937; Berkley, 1939). This is due to the reduction of the amorphous halo and the wax lines in the patterns. It may be assumed from this that the amorphous phase is soluble in the alkali and that it makes up an appreciable part of the primary wall of the cotton fiber.

SUMMARY

Longitudinal shrinkage of cotton fibers, when dried from the green to the air-dry and the oven-dry conditions, was measured on seven varieties, representing two species of cotton (*Gossypium hirsutum* and *G. barbadense*), collected at frequent intervals beginning ten days after the flowers opened. At the age of ten days the air-dry shrinkage was about 35 to 40 per cent of the "green" moist length of the fiber.

From the age of about ten days to the time secondary thickening was initiated, the shrinkage gradually decreased. One series of samples from the Mexican Big Boll variety showed little or no reduction between the thirteenth and eighteenth days. Two other series from the same variety showed the usual decline in shrinkage.

After secondary thickening started, the shrinkage decreased rapidly for the first two to five days, after which it changed very little.

All varieties showed similar trends but the rate of change was greater in the upland varieties than in the Pima or Sea Island cottons.

There was an increase of about 4 per cent in the shrinkage when the waxes were removed.

There was an appreciable increase in the shrinkage after treating the fiber bundles to remove the pectic substances.

The increase in shrinkage upon the removal of the waxes and pectic substances indicates that these substances are dispersed in or interwoven with the cellulose of the cell wall.

There was a significant decrease in the per cent shrinkage when the fibers were dewaxed and then treated in boiling 1 per cent sodium hydroxide for one hour.

At 80°C. bundles of fibers containing primary wall only, treated in 18 per cent caustic, showed a rapid increase in length for about two minutes, after which they showed a marked shrinkage which was amplified by frequent washes in water.

At room temperature similar bundles of fibers, which contained primary walls only, showed an increase in length for a few minutes when treated in 18 per cent caustic, after which the length remained constant or decreased. Alternate treatments in water and caustic resulted in progressive shrinkage with no indication of a limit to the reduction in length to be expected.

At 0° to 3°C. similar bundles of fibers increased in length when treated in 18 per cent sodium hydroxide. They increased further in length upon submerging in water at room temperature. Alternate treatments of this type caused little additional change, but what change did occur was in the nature of an increase rather than a decrease in length.

Bundles of fibers which contained secondary thickening decreased in length when submerged in 18 per cent sodium hydroxide regardless of the temperature. The rate of change increased with a rise in temperature.

Bundles of fibers which contained primary walls only elongated when treated in cuprammonium solution. The increase in length was as much as 66 per cent of the dry length of bundles. These bundles expanded very little laterally until after they were washed in water and resubmerged in the cuprammonium solution.

Bundles of fibers which contained secondary thickening shrank in length when submerged in cuprammonium solution. They swelled laterally and soon ruptured to form a jelly.

In no instance did the bundles once dried to the air-dry or oven-dry condition swell to their original green length, regardless of the swelling agent or treatment.

These results confirm the microscopic and x-ray studies which show that the crystalline cellulose of the primary wall lies transverse to the long axis of the fiber or in a low spiral around the fiber.

They also indicate that only a small percentage of the primary wall is crystalline cellulose.

DRAWING GUIDE FOR ZINC ETCHINGS

Letters, lines, and dots in relation to reduction for the printed page. Top—Reduction to 1/4. Middle—Reduction to 1/2. Bottom—Original size.

Reprinted by permission of the authors from: RIKER, A. J., and REGINA S. RIKER. 1936. *Introduction to research on plant diseases*. 117 p. Published by the Authors, Department of Plant Pathology, University of Wisconsin, Madison, Wis.

Note that thin black lines hold up fairly well in reduction, but that small black dots and small white spaces between black lines or dots may be lost. If placed too close together, dots and lines produce black blotches when the drawing is reduced. Keep the shading rather open. The degree of reduction needs to be known before the drawing is inked in.

Delicate shading may be obtained if the size and spacing of the dots are adjusted to the degree to which the drawing is to be reduced.

CHANGES IN THE METABOLISM OF WHEAT LEAVES INDUCED BY INFECTION WITH POWDERY MILDEW¹

Paul J. Allen

THE POWDERY mildews infecting wheat are parasites whose nutritional requirements are extremely exacting. These requirements are satisfactorily met in wheat leaves which are adequately supplied with carbohydrate (Trelease and Trelease, 1929), but not in leaves whose carbohydrate supply is deficient. It is, therefore, probable that the development of mildew is closely related to the carbohydrate metabolism of its host, and that a knowledge of this metabolism may throw some light on the nature of the host contributions of importance in the development of the parasite. A study has, therefore, been made of some aspects of the carbohydrate metabolism of wheat leaves as they are influenced by mildew and as they in turn influence the development of mildew. Respiration, respiratory quotients, photosynthesis and chlorophyll content, and glucose, sucrose, and starch have been measured at frequent intervals from the time of infection until the death of the leaves. The peculiar changes leading to the formation of green islands have also been followed, and are discussed in this paper.

MATERIALS AND METHODS.—*Growth of the plants.*—All of the wheat plants used in these experiments were grown in full strength Hoagland's solution in two-quart jars. The early series were grown in the greenhouse, the later series in a control chamber.² In the latter the temperature was kept at $19 \pm 2^\circ\text{C}$., the humidity at 70 ± 10 per cent, and the plants were illuminated for sixteen hours daily with a circle of eleven 30-watt daylight fluorescent lamps supplemented with seven red lamps. These gave an intensity of approximately 150 foot candles. For series F a somewhat higher intensity was obtained using six additional daylight lamps. In table 1 is presented a summary of the culture conditions and the kind of seed used in the different series.

The strain of *Erysiphe graminis tritici* used in this study is highly pathogenic for Axminster and, according to Mains' classification (1933), is, therefore, strain number two. Inoculations were made by painting spores on one side of the leaf with a dry camel's hair brush. In this way the density of inoculation could be roughly controlled, though never with great accuracy. With heavy inoculations differences in the actual number of colonies per cm.² be-

came less significant, as shown by the even tenor of changes in heavily inoculated leaves.

Handling of experimental material.—Manometric experiments were always begun between 8.30 and 9.30 a.m. and required a total of four to five hours to complete. The first foliage leaf, which has been dealt with exclusively in these experiments, was removed from the seedling, one to two centimeters of the base and tip were discarded, and the rest of the leaf was cut into two or three pieces in order to fit the experimental vessels. The error involved due to loss of water while weighing was minimized by standardizing the weighing procedure, but may still have been great enough to account for some of the variability experienced throughout these investigations. In series A_c and A the chlorophyll content was determined on the same piece of leaf whose respiration and photosynthesis were measured. In series D and E one of the two or three pieces of each leaf was cut longitudinally and the two halves used respectively for measurements of photosynthesis and chlorophyll content. The measurements of respiration were made, using one of these halves together with the remainder of the leaf. Usually the remainder of the leaf was removed before measuring photosynthesis, in order that the rate of gas exchange should be suitable.

Determination of chlorophyll content.—The chlorophyll content was determined by a method similar to that of Emerson (1929). After boiling for two minutes in distilled water, weighed samples were extracted until white in commercial methyl alcohol. The per cent transmission of the resulting solutions was measured at 670 m μ with a Bausch and Lomb spectrophotometer. The density, D, in arbitrary units, was obtained from the transmission, T, from the relation $D = \log 1/T$. The values of D were converted to moles and expressed as the chlorophyll content of one milligram of fresh leaf tissue, using a conversion factor obtained by simultaneously determining the transmission and the Mg content of a methyl alcohol extract of two kilograms of seedling wheat leaves. The extract was purified of inorganic Mg by transferring to toluene and washing repeatedly with distilled water. Determinations of this factor were made on two separate samples of wheat and yielded values which differed from each other by only 5 per cent. The two were therefore averaged, giving a conversion factor of 23×10^{-9} , which is the moles of chlorophyll per ml. which would give an absorption of 1.0.

Manometric technique.—All measurements of gas exchange were made with a Fenn microvolumeter at 22°C . The experimental conditions were similar to those described previously (Allen and Goddard,

¹ Received for publication December 16, 1941.

Contribution from the Department of Botany, University of California, Berkeley, California.

I wish to express my thanks to Prof. A. R. Davis for his generous support of this research project, and to Dr. L. C. Marshall for advice and help in obtaining uniform light intensity.

² A description of this control chamber will be published at a later date.

1938b). The actual temperature control was $\pm 0.002^\circ$ in the dark and $\pm 0.005^\circ$ when the lights were on. The pieces of leaf were floated on 2 ml. of phosphate buffer at pH 6.0 and their O_2 consumption measured with 10 per cent KOH in the side arm. CO_2 production was measured with the same tissues by determining the difference between the change of gas volume with and without KOH in the side arm.

After the respiratory measurements were made, the air in the experimental vessels was replaced with an atmosphere containing 5 per cent CO_2 and 95 per cent N_2 , and photosynthesis was measured by a method similar to that of Warburg (1919), assuming a photosynthetic quotient of 1.0.³ The source of illumination was a bank of 200-watt frosted Mazda incandescent bulbs, whose light entered the bath horizontally through a window in the front and was reflected through an angle of 90° by a glass mirror hung beneath the experimental vessels. The intensity was varied by moving the bank away from the front of the bath. The actual intensities at the base of the vessels were measured with a Weston photronic cell. For measurements of photosynthesis in the range of limiting light intensities, the power supply to these lamps was regulated by means of four RCA Radio-tron ballast tubes arranged in parallel with each other and in series with the lamps. With this circuit a uniform output of 116 volts and 8.20 amperes was obtained over an input range of 150 to 160 volts.

Carbohydrate determinations.—Sugar and starch analyses were made by the ferricyanide-ceric sulfate titration method, using setopaline C as indicator. In the preparation of extracts the procedure described by Hassid (1937) was followed. After removing the alcohol from the sugar extracts and clarifying, the solutions were made up to 20 ml., half of which was immediately analyzed for reducing sugars. The remainder was inverted for $1\frac{1}{2}$ hours at $38^\circ C$. with invertase and the total sugars then determined. The reducing sugars were calculated as glucose in both cases, using a conversion factor of 39.15 mg. glucose equivalent to 1 ml. of molar ceric sulfate.

For starch determinations, the dried residue left after extracting the sugars was ground to a fine powder, heated in distilled water on a steam bath for one hour, and the suspension then made up to volume. An aliquot was removed for a blank, the remainder was hydrolyzed for $1\frac{1}{2}$ hours with salivary amylase, and the suspension clarified and filtered. To the blank aliquot was added the proper amount of salivary amylase which had been heated to $100^\circ C$. for three minutes. Starch was calculated as maltose, using a conversion factor 1.2 times the glucose factor (Giragosintz, Davidson, and Kirk, 1936).

The I-KI test for starch was used in determining the distribution of starch in infected leaves after removal of the chlorophyll. Although the appearance of a discoloration with I-KI is not incontrovertible evidence of the presence of starch, it was interpreted

³ The photosynthetic quotient of wheat leaves was determined in four cases, and yielded values of .98, .94, .90, and .90.

as such in these leaves because of the bluish-black hue of the discoloration, and because microscopic examination showed that much of the color was in the plastids. The mildew spores, on the other hand, stained a reddish brown.

Method of handling data.—The variability in the experimental material is in itself frequently of interest, and is, therefore, given in full in the following figures. Each curve is drawn through the daily average of all determinations on similar leaves, and through each point on the curve a vertical line indicates the range of individual determinations.

Since the ratio of photosynthesis to respiration in healthy leaves is so high (about 100:1), no correction for respiration has been made in the normal photosynthesis curves. In the case of infected leaves, however, this ratio becomes as low as 3:1 and is, therefore, of much greater significance. Consequently, a respiratory correction has been introduced in the determination of all values for photosynthesis of infected leaves.

EXPERIMENTAL RESULTS.—Respiration.—The experiments of Pratt (1938) and of Allen and Goddard (1938a, b) showed that the respiratory activity of wheat leaves infected with powdery mildew is considerably higher than that of normal leaves, and demonstrated clearly that the increased respiration resides largely in the uninvaded cells of the host. From these experiments, the latter authors concluded that toxic substances are produced by the mildew, diffuse across into the underlying host cells, and there initiate metabolic changes which result in an increase in both respiration and fermentation. Their curves for the time course of respiratory changes were obtained from leaves of soil grown seedlings inoculated by dusting with mildew conidia and indicate that the initial drop from the high respiratory rate following infection is succeeded by a secondary rise. For the experiments reported in this paper plants were grown in water culture solution and inoculated more uniformly by painting the spores on one side of each leaf. If leaves are heavily inoculated in this way, so that the entire surface is soon covered with mycelium, and there is no opportunity for secondary infection, the respiratory increase reaches a maximum seven to ten days after inoculation and then declines to a level near the normal, which is maintained until the death of the diseased leaves. In figures 1 and 2 the course of these changes is shown for leaves grown, respectively, in the greenhouse in summer (series A), and in the control chamber (series D). If, on the other hand, similar leaves are lightly inoculated (20–100 colonies/cm.²), so that there is opportunity for reinfection, a secondary rise in respiration occurs before the initial decline has progressed very far (fig. 3). The respiratory changes in this series were correlated with the development of secondary infection. Nine or ten days after inoculation, the primary colonies were sporulating heavily. These spores were shed and occupied the uninfected portions of the leaf, and at the time of the secondary maximum, six

or seven days later, many new colonies which were sufficiently mature to exert a strong effect on respiration had appeared all over the leaves.

These observations offer an adequate explanation for the secondary rise reported by Allen and Goddard in 1938. They also show that portions of diseased leaves which are not actually occupied by mildew colonies retain for some time their ability to undergo a respiratory increase. This is in accord with the observation that uninfected segments of diseased leaves show no increase in respiratory rate (Allen and Goddard, 1938b), and offers additional evidence for the restricted spread of mildew toxins.

Wheat plants grown in the greenhouse in winter are much less vigorous than those grown under more adequate light conditions. Associated with this unhealthy condition of the host plant is a decrease in the response to heavy inoculation with mildew. A relatively small number of colonies develop, so that the leaves give the appearance at first of having been lightly inoculated. The curve in figure 4 shows the small increase in respiration in such leaves. A maximum is reached earlier than in more vigorous plants, but the infected leaves survive about the same length of time as healthy leaves which have been heavily inoculated.

An increased respiration in other plants infected with obligate parasites has been found by Reed and Crabill (1915), Iljin (1923), Maresquelles (1928), Kourssanov (1928a), Yarwood (1934a, b), and other investigators.

The respiratory quotient.—In the preceding discussion only measurements of O_2 consumption have been reported. These measurements give no clue as to the nature of the substrate which is being oxidized. In two series the CO_2 production and O_2 consumption were, therefore, measured consecutively on the same tissue samples, and the R.Q.'s were calculated. The curves of figures 5 and 6 show the changes in R.Q. in the lightly infected leaves of series E and the heavily infected leaves of series D. (For the O_2 consumption in these two series see figures 2 and 3.) In series D the R.Q. is greater than 0.9 until after the respiratory maximum is reached, and drops to a fairly constant value around 0.85 after the decline in O_2 consumption sets in. The high R.Q. on the eighth day after inoculation occurs at the time of the first decline in respiration and is probably significant. In the lightly infected leaves of series E the R.Q. is high at the time of inoculation. This high R.Q. appears to be characteristic of young leaves. Before the respiratory rate has risen very far, the R.Q. reaches a value of about 1.05 which is maintained, with minor fluctuations, until respiration is at a maximum. Thereafter it decreases slightly, but still remains fairly close to 1.0.

These figures indicate that carbohydrate is the primary substrate being oxidized, at least during the phase of increasing respiration. In heavily infected leaves there is evidence for a definite change to the oxidation of additional substrates as the respiratory maximum is reached. But in lightly in-

fect leaves carbohydrate seems to be the primary substrate even after the first maximum in respiration is passed. The maintenance of an R.Q. close to 1.0 is associated with a continued high respiratory rate (cf. fig. 3).

The respiratory changes bear an interesting relation to the growth of the parasite. The major part of the vegetative growth of mildew colonies takes

Fig. 1-6.—Fig. 1-4. Changes in respiration in plants inoculated with mildew.—Fig. 1. Marquis plants grown in the greenhouse in August, heavily inoculated when ten days old.—Fig. 2. Axminster grown in control chamber, heavily inoculated when twelve days old.—Fig. 3. Pure line Marquis grown in control chamber, lightly inoculated when twelve days old.—Fig. 4. Marquis grown in the greenhouse in December, heavily inoculated when twelve days old.—Fig. 5-6. Changes in respiratory quotient of the leaves of series E and D, respectively.

place during the phase of increasing respiration, and an arrest in their growth appears concurrently with an arrest in the respiratory increase and a change to the oxidation of non-carbohydrate substrates. This is true whether the leaves are heavily or lightly inoculated. Since the arrest occurs earlier in heavily infected leaves, the individual colonies on such leaves never become as large as they do on lightly infected ones.

Photosynthesis.—The influence of parasitic infection on the photosynthesis of higher plants has been studied by several investigators, with diverse results. Kourssanov (1928b) measured the photosynthetic activity of wheat infected with *Ustilago tritici* and found it to be slightly higher than that of normal wheat. Iljin (1923), on the other hand, found

Fig. 7-15.—Fig. 7-9. Changes in photosynthesis/mg. fresh weight of normal (series A_c) and infected (series A, D, E) wheat leaves.—Fig. 7A_c. Same as figure 9.—Fig. 13-15. Changes in photosynthetic efficiency in normal (series A_c) and infected (series A, D, and E) wheat leaves.—Fig. 13A_c. Same as figure 7A_c.—Fig. 13A. Same as figure 7A.—Fig. 14. Same as figure 8.—Fig. 15. Same as figure 9.

a decrease in the photosynthesis of sunflower leaves infected with *Puccinia Helianthi* and of clover leaves infected with *Erysiphe Marthii*. Similarly, Reed and Crabill (1915) found that the photosynthesis of apple leaves infected with *Gymnosporangium Juniperi-virginianae* was lower than normal.

In order to make a comparison of the photosynthetic ability of the cells of diseased and healthy plants, it is necessary that the measurements be made when no external factors are limiting the rate. Preliminary experiments were, therefore, carried out to determine the conditions of CO₂ concentration, stomatal opening, and light intensity which would allow maximum photosynthesis of wheat leaves. It was found that an increase of CO₂ above 2 per cent by volume had no effect on the photosynthesis of the leaf pieces used in these experiments. The size of the stomatal aperture under differ-

ent conditions was determined with a reflection objective attached to a compound microscope. In leaves which had just been removed from the seedlings the stomata usually appeared closed; after an hour's exposure to strong light in the saturated atmosphere of the experimental vessels, the stomata were wide open; if exposed to lower illumination they opened more slowly and never as widely. Yet the rate of photosynthesis at a given light intensity did not change while these changes in stomatal aperture were going on. It was, therefore, considered that stomatal opening would not enter as a factor limiting the supply of CO₂ under the conditions of these experiments. Photosynthesis-light intensity curves were obtained, and it was found that the rate of CO₂ reduction was proportional to light intensity up to about 500 foot candles, and between 500 and

600 foot candles the curves gradually sloped off to a plateau.

It is interesting to compare the behavior of the isolated leaf pieces used in these experiments with that of entire plants of the same variety of wheat. Hoover *et al.* (1933), using seedlings of Marquis wheat, found that photosynthesis was dependent on light intensity even up to 2,000 foot candles when the CO₂ concentration was high (.15 per cent). Since photosynthesis was expressed in arbitrary units, it is not possible to compare their maximum values with those for leaf pieces. Brackett (1935), however, states that the photosynthesis respiration ratio was 1:35, while this ratio in the present experiments was about 1:100. Assuming a similar rate of respiration in the two cases, these figures indicate that the maximal rate of photosynthesis of leaf pieces at 600 foot candles is nearly three times as great as that of entire seedlings at 2,000 foot candles. The difference is probably due to the fact that much thick tissue and tissue relatively poor in chlorophyll is included in the entire plant and to the shading of tissues in the stem and near the leaf bases. The behavior of the isolated leaf is much more like that of unicellular green plants, such as *Chlorella* (Warburg, 1919) and the diatom *Nitzschia* (Barker, 1935).

Photosynthesis per milligram fresh leaf.—The photosynthesis of normal leaves declines gradually and irregularly with age (fig. 7A_c). Although there are large diurnal fluctuations, the values for a given day agree with each other quite closely. This is equally true for plants grown in the greenhouse or in the control chamber. The origin of these fluctuations is, therefore, not in changes in the environment but in internal changes.

If leaves are heavily inoculated with mildew, their ability to carry on photosynthesis under conditions of light saturation soon begins to decrease. In figure 7A the photosynthesis of Marquis leaves grown in the greenhouse is plotted against age of infection. It drops rapidly from a high value of 21.0 mm.³/mg./hr. two days after inoculation to a value of about 6.0 on the seventh day. Subsequently there is a continued slow decline until the death of the leaves, about two weeks after inoculation. The response of Axminster wheat grown in the control chamber is very similar (fig. 8), except that the decline does not start until three days after inoculation and is not checked until eight days after inoculation, when it has reached a value of about 3.0 mm.³/mg./hr.

If leaves are lightly inoculated, the influence of the mildew appears more gradually, and the decline in photosynthesis continues for a longer period than in heavily infected leaves (fig. 9). Before the leaves die, however, photosynthesis becomes just as low as in more severely infected leaves. The variability in this series is large because of the greater differences between the actual number of colonies on each leaf.

Since the above measurements were made under conditions of light and CO₂ saturation, they repre-

sent changes in the activity of the Blackman reactions. The effects of the mildew may, therefore, be extended to include a more or less gradual impairment of the activity of the dark reactions.

Chlorophyll content.—The chlorophyll content of normal leaves is, like the rate of photosynthesis, a function of the age of the seedling. Figure 10A_c shows the course of changes in chlorophyll of normal leaves of Marquis grown in the greenhouse. These changes follow a more uniform trend than the changes in photosynthesis. Heavy inoculation with mildew results in a rapid destruction of chlorophyll (fig. 10A and 11). The curves for chlorophyll content are quite similar in their general features to the curves for photosynthesis. This is also the case for lightly inoculated leaves (fig. 12), whose chlorophyll content, like their photosynthetic rate, drops more slowly. There are, nevertheless, certain obvious differences between the curves for chlorophyll content and those for photosynthesis. In series A there is an increase in chlorophyll between the fifth and sixth days after inoculation but no corresponding increase in photosynthesis. Since photosynthesis and chlorophyll content were both determined for the same leaf pieces, this difference is not due to the variability of different samples. During the last few days of each series there is a slight increase in chlorophyll but no corresponding increase in photosynthesis. This difference is particularly clear in series D.

Photosynthesis per mole of chlorophyll.—From the values for photosynthesis and chlorophyll content the photosynthetic efficiency or the photosynthesis per mole of chlorophyll may be calculated. If changes in the rate of photosynthesis are determined by changes in chlorophyll content alone, the photosynthetic efficiency will remain constant. If such changes represent alterations in other parts of the photosynthetic mechanism, the photosynthetic efficiency may change. The destruction of chlorophyll which is not functioning at its maximum capacity (because of the slowness of the dark reactions) will cause an increase in photosynthetic efficiency. Or if the inactivation of other parts of the photosynthetic mechanism proceeds more rapidly than the destruction of chlorophyll, there may be a decrease in photosynthetic efficiency.

The value for photosynthetic efficiency have been calculated for each leaf used in series A_c, A, D, and E. The individual values were averaged, and the resulting curves are plotted in figures 13 to 15. The changes in photosynthetic efficiency of normal leaves show a striking parallelism with the changes in photosynthesis of the same leaves (cf. fig. 7). The fluctuations in photosynthesis of these leaves do not, therefore, depend on variations in chlorophyll, but on variations in other parts of the photosynthetic mechanism. Diseased leaves, on the other hand, present a different picture. In the heavily infected leaves of series A and D there is an increase in the photosynthetic efficiency followed by a decrease, and about one week after inoculation the efficiency drops

Fig. 16-18.—Fig. 16. Photosynthesis at incomplete light saturation (150 foot candles) of Marquis wheat leaves grown in the greenhouse in August. Note the greater uniformity in the curves for normal leaves (series A_C) when light intensity is the limiting factor.—Fig. 17-18. Changes in carbohydrates in leaves of Marquis seedlings grown in control chamber, and the relation between glucose content and respiration. Figures 17A and 18A represent the changes in sucrose and glucose, respectively, in normal wheat. The other curves represent changes in heavily infected leaves of series F. All plants were grown in the control chamber. Note the close parallelism between glucose content and respiration.

below its original level. In the lightly infected leaves of series E it does not increase, nor does it drop appreciably below normal until late in the course of the infection. A definite drop appears on the same day that the final decline in respiration starts. This figure, like the others for lightly infected leaves, shows considerable variability in the samples taken on any given day. The difficulty in obtaining uniform inoculation makes it impossible to carry the interpretation of these curves very far.

The absence of any relation between photosynthetic rate and chlorophyll content is in agreement with the recent work on photosynthesis (Ruben, Kamen, and Hassid, 1940) which indicates that CO_2 is fixed by some compound other than chlorophyll, and that this compound may be varied independently of the chlorophyll content.

Photosynthesis in low light.—The changes in photosynthesis at 180 foot candles, where the normal rate is somewhat less than half maximum, were determined for series A_C and A (Marquis seedlings grown in the greenhouse in summer). The resulting curves are shown in figure 16. Here the photosynthesis of normal leaves declines slowly over a two-week period, but does not show nearly as many fluctuations as under a saturating intensity of light. Calculation of the photosynthetic efficiency of these leaves yields an even more uniform curve in which many of the fluctuations which appeared in high light are absent. These curves conform with the expected trend of photosynthesis in normal leaves when light intensity is a limiting factor. In low light the dark reactions proceed more rapidly than is necessary to take care of the products of the light reactions, and variations in their activity are, therefore, not reflected by corresponding changes in the rate of photosynthesis. Variations in the chlorophyll content are, however, effective in altering the observed rate of photosynthesis, as the constancy of the values for photosynthetic efficiency shows.

In diseased leaves, the curve for photosynthesis does not show any clear cut difference from that obtained in high light. Calculation of the photosynthetic efficiency, however, yields a curve which does not drop below the normal until eleven days after infection, instead of seven days afterwards as in high light. Here again photosynthesis is more dependent on chlorophyll content than it is in high light, and not until the dark reactions have been slowed down considerably more than in high light does their activity exert a rate-determining effect on the overall process of photosynthesis.

Glucose and sucrose.—The sugar content of normal leaves grown in the control chamber declines gradually after the leaves are mature (fig. 17A and 18A). Upon inoculation with mildew there is an accumulation of both glucose and sucrose (fig. 17B and 18B). In the plants of series F sucrose has increased, four days after inoculation, from .32 per cent of the total fresh weight to 1.08 per cent, but there is as yet no appreciable increase in glucose. Subsequently sucrose continues to accumulate, and glucose also

increases greatly. The disappearance of soluble sugars, like their appearance, is brought about first by a decrease in sucrose; while the glucose tends to maintain a more uniform concentration. This behavior of the soluble sugars is similar to that observed by Hassid and McCready (1941), who have recently demonstrated that changes in the sugar content of barley leaves appear primarily as changes in the amount of sucrose, while glucose tends to remain at a fixed level.

The changes in respiration in series F are shown in figure 18C. Respiration, glucose, and sucrose are all at a maximum on the same day, six days after inoculation. The changes in respiration show a good correlation with changes in glucose content, but no relation to sucrose. The correlation is particularly close up to the respiratory maximum. After this point a close correlation is not to be expected, because, as was pointed out above, in heavily infected leaves carbohydrate is not the only respiratory substrate during the phase of declining respiration. These experiments point to the glucose content as a primary factor in determining the respiratory rate. There is no correlation between total sugars and respiration, such as Krotkov (1939) found in starving leaves of Little Club wheat.

Starch.—The normal wheat leaf does not form starch except in the guard cells, where the chloroplasts appear as dark bluish-black granules when stained with I-KI. But as soon as a mildew colony becomes established on the leaf, a dark discoloration appears immediately underneath and extending slightly beyond the mycelium. By the time that the fungus is sporulating, five or six days after inoculation, the chloroplasts of cells near a mildew colony show the same dark staining material that appears in the guard cells. Its color and its association with the chloroplast indicate that it is starch, although other substances as well contribute to the dark discoloration in diseased leaves. At about the time when respiration is highest, starch is most abundant, and subsequently it disappears. But the dark discoloration around the mildew colonies persists even after the disappearance of recognizable granules containing starch. Dr. Pratt⁴ has observed similar areas of discoloration when diseased leaves are stained with other reagents, such as methylene blue. The localized spread of the mildew toxins could not be better demonstrated than by these areas of discoloration around each colony (fig. 19). Not only is the spread localized, but it is more restricted laterally than it is longitudinally. Lengthwise of the leaf, transport is facilitated by the elongated cells of the epidermis and vascular tissues, so that the shape of the discolored areas is elongate ellipsoidal. The close correspondence between the form of the colonies and the form of the areas which show by the deposition of starch that they have been affected by the mildew toxins suggests very strongly that the changes produced by the mildew are necessary for the rapid development of the parasite.

⁴ Private communication.

Quantitative analyses for starch were made on the leaves of series F after the sugars had been removed. The amount of starch in normal leaves is too small to measure, while in the diseased leaves it accumulates to a maximum value of about .2 per cent (fig. 17C). Like the iodine tests these analyses show a maximum accumulation of starch at the time of the

Fig. 19. Leaves at various stages after inoculation with mildew, showing the distribution of areas stained with I-KI. The age of the infection is indicated by the figures on the right. Each dark spot represents the effect of a mildew colony. Note the longitudinal spread of the discoloration under young colonies (seven days). In older leaves most of the starch is gone (fifteen to nineteen days) except where secondary infection has developed (nineteen days).

most rapid respiration and the greatest accumulation of soluble sugars.

An abnormally large amount of starch and sucrose is found in mildewed wheat plants only during the first eight days after infection. Thereafter both starch and sucrose disappear completely. Observations made at an early stage of the disease would, therefore, lead to the conclusion that starch and sucrose had increased as a result of infection, while if they were made later they would lead to the conclusion that sucrose had been destroyed. This may account in part for the divergent results of previous

investigators, who have sometimes found that parasitic infection caused an accumulation of carbohydrate in the host (Schellenberg, 1911) and at other times have found a decrease (Robinson, 1913, and others).

Formation of green islands.—Green islands are localized areas containing chlorophyll in leaves which have elsewhere become chlorotic as a result of parasitic infection. They were first reported by

Fig. 20. The development of green islands on infected leaves. Photographs taken from the uninfected side of the leaf. Under the young colonies chlorotic spots appear (seven, nine days); later green spots appear in the center of the chlorotic areas (eleven to fifteen days), and eventually are left as green islands when the areas of chlorosis fuse (seventeen, nineteen days).

Cornu (1881) on leaves of several deciduous plants infected with both obligate and facultative parasites, and have since attracted the attention of many investigators. They are particularly striking in leaves infected with mildew when the carbohydrate reserves of the host are low. For instance, if diseased leaves are left in the dark for a couple of days, the leaves quickly become chlorotic except underneath the mildew colonies; or, if photosynthesis is particularly low in the greenhouse, as it is during winter or in heavily shaded leaves, green islands appear.

In the normal course of development on vigorous leaves a mildew colony first causes a destruction of

chlorophyll in the cells immediately beneath the mycelium (fig. 20, seven and nine days). As the colony enlarges, the chlorotic area also enlarges, spreading somewhat faster than the fungus. At the time when starch begins to disappear, as indicated by the iodine staining (which is also the time of disappearance of soluble sugars), a spot of green appears in the center of each chlorotic area. The green spot enlarges, leaving a ring of yellow surrounding it (fig. 20, thirteen and fifteen days). With the continued spread of the chlorotic areas, adjacent regions of chlorosis fuse, eventually occupying the entire leaf except for the green islands underneath the mildew colonies (fig. 20, seventeen days). Green islands do not, therefore, represent merely the retention of chlorophyll in cells affected by the mildew, but they actually are areas in which the chlorophyll was first destroyed during the phase of rapidly changing host metabolism, and was subsequently re-formed. Reference to figures 9, 10, and 11 shows that the total chlorophyll content stops decreasing when it is still at a fairly high level, and, in the case of series D, figure 10, there is definitely an increase above the low level reached ten days after infection. The fact that, at the same time, photosynthesis continues to decrease (fig. 6–8) indicates that the chlorophyll which appears in the green islands is not photosynthetically active.

Discussion.—The changes in host metabolism brought about by mildew infection divide themselves conveniently into two phases, which we shall refer to as the first and second phases of the disease. The characteristics of host metabolism in these two phases are fundamentally different and appear to be separated by a rather sudden disorganization of the normal metabolic relationships at the time of the maximum in respiration and carbohydrate accumulation. Up to that time the changes which occur are primarily quantitative; subsequently marked qualitative changes also occur. During the first phase the host affords an excellent substratum for mildew growth and the vegetative expansion of the mildew is rapid; subsequently little vegetative growth occurs, and the ability of the mildew to sporulate drops off. These two phases are most distinct in heavily infected leaves, where the entire leaf soon comes under the influence of the mildew toxins, and the picture is not complicated by secondary infection.

The first phase is characterized by an increase in the rate of oxidation of carbohydrate; by an increase in glucose, sucrose, and starch; by a constant glucose respiration ratio; and by a destruction of chlorophyll which is closely followed by a decrease in photosynthesis but not by a decrease in photosynthetic efficiency. The time during which these changes proceed seems to correspond with the time required for the mildew toxins to spread widely throughout the leaf, because the first phase lasts considerably longer in lightly infected leaves, and its features predominate as long as new leaf areas are coming under the influence of growing mildew

colonies. The fact that the increase in respiration and the decrease in photosynthesis proceed independently of each other during this phase even though they both reduce the normal supply of carbohydrate, indicates that this is a period during which a third agent, presumably the mildew toxins, is a major factor determining the trend of these processes. Only after photosynthesis has been reduced to a very low level does the effect of carbohydrate starvation enter as a factor modifying the effect of the mildew toxins on the carbohydrate breakdown and the carbohydrate content of the leaves.

The second phase is opened by a rather abrupt change in all of the above mentioned relationships. The rate of cellular oxidations drops off rapidly, and a decrease in R.Q. indicates that now other substrates besides carbohydrate are being oxidized. This is corroborated by the fact that respiration is no longer strictly proportional to glucose concentration (fig. 18B and C). All of the three types of carbohydrate investigated decrease in quantity, sucrose and starch disappearing completely. The rate of photosynthesis continues to drop, but now more rapidly than chlorophyll, so that the photosynthetic efficiency falls below normal. During the early part of this phase the cells first affected by the mildew form new chlorophyll, which is, however, inactive in photosynthesis. Vegetative growth of the mildew slows down, and soon afterwards undisturbed colonies present the aspect of tiny craters, because the failure of the central part of the colony to continue forming conidia results in a small central depression surrounded by the chains of conidia on the younger hyphae near the periphery. It is during this second phase of the disease that green islands first appear.

The experiments of Trelease and Trelease (1929) demonstrated very clearly the dependence of mildew on an adequate supply of carbohydrate to the host. The above experiments, which were carried out using the same strain of mildew used by the Treleases, show that, in the development of mildew on intact plants, the fungus does not grow merely on the carbohydrates normally present in the wheat leaf but that, by preventing their removal from the leaf, it plays an active role in securing for itself an abundance of carbohydrates. The advantage which this gives to the mildew may result directly from the utilization of carbohydrate by the fungus. Since, however, the host is at the same time respiring carbohydrate rapidly, it is equally possible that other substances resulting from the metabolism of these sugars

are of vital importance in the vegetative development of the mildew. In any case, the high carbohydrate content and the high respiration are intimately connected with mildew growth. This is clear from the close correlation between the periods of mildew growth and the periods of carbohydrate accumulation and increasing respiration. In winter grown plants the phase of increasing respiration (and, therefore, presumably of increasing sugar content) does not last very long and the rate does not increase greatly. On such leaves the mildew colonies develop slowly and never become very large. On heavily infected leaves of vigorous seedlings the colonies develop more rapidly and become larger, while on lightly infected leaves, in which the first phase lasts much longer, the colonies reach the largest size of all.

The effects of the mildew are not, however, all to its advantage. The increased respiration resulting from the accumulation of carbohydrate together with a decreasing rate of photosynthesis eventually leads to the depletion of the host carbohydrate reserves. At the same time, either as a result of, or as a corollary to the increased respiration, other components essential to the life of the cell are destroyed. If the leaves are heavily infected, they may die before the mildew has a chance to form resistant ascospores, and its only method of reproduction is by the abundant but non-resistant conidia.

In the normal wheat leaf the rate of carbohydrate synthesis far exceeds the rate at which it is respired. Very little is stored in the leaf as soluble sugar and none as starch, so that the majority of it must be exported to other parts of the plant which do not form their own carbohydrate, such as the root and the growing parts of the shoot. The accumulation of sugars and starch and the more rapid respiration in diseased leaves must depend on some influence of the parasite which prevents the normal export of soluble sugars. In fact, since the rate of photosynthesis is dropping rapidly while an increase in the accumulation and breakdown of carbohydrates is going on, there is even some question as to whether the photosynthesis of the diseased leaf is sufficient to supply the demand. In order to give some idea of the relative amounts of carbohydrate produced and those used up at different times after inoculation a balance sheet has been prepared and is shown in table 2. All except the values for photosynthesis are taken from series F. Since photosynthesis was not measured in that series, the figures from series D, which

TABLE 1. Summary of the culture conditions in different series.

Series	Fe source	Growth conditions	Seed	Age at inoculation
A and A _e	Fe tartrate	Greenhouse in August	Marquis	10 days
B	Fe tartrate	Greenhouse in December	Marquis	10 days
D	Fe citrate	Control chamber	Axminster	12 days
E	Fe citrate	Control chamber	Marquis, pure line	12 days
F	Fe citrate	Control chamber	Marquis, pure line	12 days

TABLE 2. *The figures in this table represent moles of carbon per unit weight of leaf per day. The first two rows give the amounts of carbon synthesized and respired on successive days after inoculation. The third is the excess of carbon synthesized over that respired. In the fourth row is given the amount of carbon found in the form of carbohydrate. Subtracting this from the amount not respired gives the carbohydrate available for export on any given day, shown in the last row of figures.*

has a similar respiratory curve, were used as a basis for estimation. In the control chamber CO_2 concentration was approximately atmospheric and probably, therefore, a limiting factor in photosynthesis. To allow for this the values of series D were reduced to two-thirds. Light intensity in the chamber was about 200 foot candles, which would give a photosynthetic rate one-half maximum. The figures for photosynthesis are, therefore, obtained by dividing the maximum values by one-third. The values obtained in this way show that by the time respiration and sugar content are at a maximum there is little or no surplus carbohydrate available for export. No statement concerning an actual import can be based on these figures. The fact that sugars and starch begin to disappear as soon as photosynthesis becomes too low to provide a surplus argues against a flow of sugars into the diseased leaves.

The accumulation of starch might be the result of the increased concentration of sugar. But the fact that starch is never found in normal wheat leaves (except the guard cells), while the sugar content of such leaves under unusual conditions may be as great as 2.5 per cent, indicates that other changes must take place before starch is formed. Such a change might be produced by an increase in phosphorylase, which Hanes (1940) has recently shown to be the enzyme responsible for starch synthesis in higher plants.

SUMMARY

When wheat leaves are lightly infected with mildew, the respiration curve exhibits two maxima, one corresponding to the time of maturity of the primary colonies, the other to the time of maturity of the secondary colonies.

The respiratory maximum in plants grown in the greenhouse in winter is only about one-third as great as that of plants grown under better lighting conditions.

The growth of a mildew colony is rapid during the period of increasing respiration, sugar, and starch. After these reach their peak and start declining, vegetative growth of the mildew slows down. The individual colonies on heavily infected plants, where respiration is at a maximum a week after inoculation,

are, therefore, smaller than those on lightly infected ones, where the respiration is not at its height for about two weeks.

The substrate oxidized in lightly infected leaves, as indicated by the R.Q., is mainly carbohydrate; in heavily infected leaves carbohydrate is the primary substrate up to the respiratory maximum, but thereafter other substances are also oxidized.

Mildew infection leads to a breakdown of the photosynthetic mechanism which involves both the light and the dark reactions. In heavily infected plants, chlorophyll content and photosynthesis at light saturation (600 foot candles) start dropping rapidly soon after inoculation. They do not, however, follow the same course, since the photosynthesis per mole of chlorophyll first increases, then drops off, falling below normal about a week after inoculation. In lightly infected plants at light saturation the decreases in photosynthesis and chlorophyll are more gradual, and the photosynthesis per mole of chlorophyll does not increase. About two weeks after inoculation, when respiration is declining from the second maximum, it drops abruptly. In heavily infected plants at incomplete light saturation the changes in photosynthesis are more closely related to chlorophyll content.

In heavily infected plants there is an accumulation of soluble sugars which reaches a maximum simultaneously with respiration. Sucrose accumulates more rapidly than glucose, reaches a higher level, and disappears again more rapidly.

The rate of respiration up to the maximum is proportional to the glucose content but is not related to sucrose. After the maximum, respiration is nearly proportional to glucose content but not so closely as before.

In infected wheat leaves, starch is deposited near the mildew colonies. It is most abundant at the time of the maximum in respiration and soluble sugars, and disappears as they decrease.

During the early growth of the mildew, chlorotic spots appear beneath each colony and spread outward until they fuse. Before the fusion is complete, at about the time of the respiratory maximum, chlorophyll is re-formed under the center of each mildew colony and spreads outward to form green islands,

each of which occupies an area about the size of a mildew colony.

An estimation of the excess of carbohydrate produced over the amount utilized by the leaf shows that the amount available for export decreases to zero or below at the time of the respiratory maxi-

mum. Thereafter all the carbohydrate synthesized is utilized by the leaf itself.

STUDIES ON THE BIOLOGY OF TWO SPECIES OF MAGNUSIA. II. EFFECT OF HUMIDITY ON CONIDIAL GERMINATION, GROWTH AND REPRODUCTION¹

Herman R. Sweet

IN THE previous paper dealing with the effects of temperature on spore germination, growth and reproduction, the writer (1941) pointed out that desiccation had a marked influence both on the germination of the spores and on the growth of *Magnusia nitida* Sacc. and *M. brachytricha* Ames. As a result, experiments were made to discover the degree of humidity necessary for the activity of these two fungi and to determine the limits at which germination, growth and reproduction would take place.

EFFECT OF HUMIDITY ON CONIDIAL GERMINATION.—For this study, potato-rat dung agar as described in the previous paper was used as a substratum, the agar being placed on cover glasses which were then inoculated with the conidia, inverted, and sealed to Van Tieghem cells containing various percentages of sulphuric acid, according to the procedure outlined by Stevens (1916). Three slides of each species for each relative humidity, placed in a constant temperature oven at 32°C., were examined at hourly intervals up to twelve hours, and then at twenty-four, forty-eight, and one hundred hours. The number of conidia per slide averaged 200, the two extremes being 150 and 250. The relative humidities used in the first series were as follows: 100, 91.2, 80.6, 70.4, 60.7, 49.0, and 29.5 per cent; and in the two additional series were 100, 99.5, 99.1, 98.7, 98.2, 97.5, 95.6, and 93.9 per cent.

The results of the first series of experiments, in which the wider range of relative humidities was employed, demonstrated that the conidia of both *M. nitida* and *M. brachytricha* germinated at or near 100 per cent relative humidity, with only one slide germinating at the next lower humidity of 91.2 per cent where at the end of fifty hours no conidia had germinated, but at the end of one hundred hours the spores of *M. brachytricha* on one slide showed a germination of 23.8 per cent. The range for conidial germination was, therefore, somewhere above a relative humidity of 91.2 per cent. When examined under the microscope, it was seen that the conidia kept at humidities under 91.2 per cent had lost water, as was shown by their reduced size, and conidia maintained in an atmosphere of 70.4 per cent relative humidity or lower were definitely collapsed and smaller in size than those above 70.4 per cent relative humidity.

The results of the two additional series of experiments are shown in figure 1. As is obvious from the

graph, the conidia of *M. nitida* germinated both more readily and at a lower humidity than did those of *M. brachytricha*. At a relative humidity of 99.5 per cent *M. nitida* germinated to the extent of 96.7 per cent in one of the series, and *M. brachytricha* to the extent of 91.8 per cent, whereas there was no germination of *M. nitida* in a relative humidity of less than 95.6 per cent and of *M. brachytricha* in a humidity of less than 97.5 per cent. At both 100 and 99.5 per cent relative humidities, germination had begun to take place by the end of the fourth and fifth hours, respectively, but below 99.5 per cent the time required for the initiation of germination was lengthened, the first conidia of *M. nitida* germinating at the end of six hours and those of *M. brachytricha* some time between eight and twenty-four hours. A greater percentage of germination was obtained at a rela-

¹ Received for publication January 2, 1942.

Contribution from the Laboratories of Cryptogamic Botany and the Farlow Herbarium, Harvard University, no. 205.

The author wishes to thank Dr. David H. Linder, under whose direction this work was done, for his helpful advice; and also Professor William H. Weston, Jr., for his friendly counsel.

tive humidity of 99.5 than at 100 per cent. At first thought, it would seem that a difference in humidity of 0.5 per cent would be too small to make any significant difference in the results, but Longrée (1939), in a careful series of experiments using conidia of *Sphaerotheca pannosa* var. *rosae*, also demonstrated that in humidities just under 100 per cent—that is,

at 99.0 and 98.0 per cent—there was a greater percentage of germination than at 100 per cent. In her experiments, at a relative humidity of 96.9 per cent, the spores germinated poorly, whereas at 94.9 per cent only a few (2.0 per cent) germinated. The lower percentage of germination at 100 per cent relative humidity was found to be due to free water deposited on the spores, and later experiments showed that the free water (water of condensation) caused a deficiency of oxygen. It is perfectly possible that this is the explanation for the lower percentage of germination at 100 per cent relative humidity in these species of *Magnusia*, since it was noted in the course of other experiments that a higher percentage of germination was obtained on hanging drops of agar that had little free water than on agar drops suspended in a saturated atmosphere. It was also found that conidia resting on the surface of agar drops, where the humidity is slightly lower and the supply of available oxygen greater, germinated more readily than did those below the surface of a water droplet.

The fact that a high relative humidity is necessary for the germination of many species of fungi has been pointed out by several workers. Linder (1929) found that there was practically no germination of helicosporous fungi at a humidity lower than 98.8 per cent. Melhus, Durrell and Kirby (1920) found that the teleutospores of *Puccinia graminis* did not germinate at a relative humidity below 95.6 per cent, and Maneval (1922) likewise found that a saturated atmosphere was necessary for the germination of the teleutospores of *Puccinia Helianthus* Schw.

Because in nature the fungi must be subjected to drying and wetting, it was considered advisable to test the resistance of the conidia to desiccation under conditions existing in the preliminary experiment as contrasted with drying in the room. To this end, the conidia that had been subjected in the early experiments to relative humidities of 91.2 per cent and below were transferred at the end of one hundred hours to other Van Tieghem cells in which the sulphuric acid solutions had been replaced by distilled water, thereby establishing a saturated atmosphere. The conidia then absorbed water to such an extent that at the end of twenty-four hours they had returned to approximately their normal size and some had germinated. Those which failed to germinate also failed to show the characteristic swelling which occurs prior to germination.

This experiment reaffirmed the greater ability of *M. nitida* to recover from adverse conditions, for this species showed not only a higher percentage of germination than did *M. brachytricha*, but also germination occurred on slides kept previously at the lower humidities. Of the slides formerly kept at 91.2 per cent relative humidity, the conidia of *M. nitida* alone made a good recovery, achieving a germination of 75.8 per cent at the end of twenty-four hours, and 95.0 per cent at the end of forty-eight hours, whereas those of *M. brachytricha* showed a 34.6 per cent germination at the end of twenty-four hours,

and only 50.0 per cent in twice that time. Of the conidia which had been kept at a relative humidity of 70.4 per cent for one hundred hours, those of *M. nitida* showed a 12.6 per cent germination at the end of twenty-four hours, and a 40.0 per cent germination at the end of forty-eight hours in a saturated atmosphere, but those of *M. brachytricha* showed only a 25.0 per cent germination at the end of forty-eight hours. Of the conidia previously kept at a relative humidity of 60.7, there was no germination of *M. brachytricha*, but there was a 10.0 per cent germination of *M. nitida* at the end of forty-eight hours. In all cases, there was a considerable delay in the initiation of germination, and the time required for the conidia to reach their maximum germination was greatly lengthened.

To compare the effect of drying at higher temperatures with that at room temperature, conidia from cultures approximately two weeks old were placed on glass slides in Petri dishes, each of which was kept at a specified temperature for a definite period of time. *M. nitida* was again revealed as able to withstand adverse conditions somewhat better than *M. brachytricha*, since conidia kept at 24°C. for forty-eight hours germinated to the extent of 94.6 and 93.0 per cent for *M. nitida* and *M. brachytricha* respectively, while, when the conidia were kept at 24°C. for ninety-six hours and then at 38°C. for twenty-four hours, the germination amounted to 70.2 and 47.0 per cent for the two respective species. However, the difference between the two species was not so great when the conidia were dried for ninety-six hours at 24°C. and for sixty hours at 38°C., since the percentage of spore germination of *M. nitida* was then 43.0, whereas that of *M. brachytricha* was 41.2. It is apparent that the harmful effects of desiccation became manifest more quickly at the higher temperatures, since, when the conidia were kept protected in a Petri dish at room temperature for a year and a half, during which time the temperature varied from 20 to 24°C., 45.0 per cent of the conidia of *M. brachytricha* and 48.5 per cent of *M. nitida* germinated. When these results are compared with those of the previous experiments, it would seem that a year and a half of desiccation at room temperature had the same effect as sixty hours at 38°C.

Low humidity has been noted by other investigators as having an almost universal influence upon the viability of spores. Linder (1929), for example, found that *Helicoma Mülleri*, *Helicosporium aureum* and *H. gracile* did not germinate after being kept for nine months at the humidity and temperature of the laboratory. He did find two of the species germinating slightly after a similar exposure of eleven months: *Helicomycetes scandens* and *Helicoma Curtissi*, the latter to an extent of 4.8 per cent. Newhall (1938) found the conidia of *Peronospora destructor* able to survive several days at humidities above 70.0 per cent at room temperature. Sawyer (1931), however, found that *Entomophthora sphaerosperma* did not remain viable unless placed at a low temperature.

It would be inaccurate to conclude from these experiments that in nature such a high degree of atmospheric humidity is essential to the germination of the conidia, since the porosity and moisture of the substratum would play an important part in germination, for a porous substratum and an abundance of capillary water would allow the fungi to germinate at humidities apparently below those at which germination occurred under laboratory conditions. A hanging droplet of nutrient agar would naturally

Fig. 2. The effects of various humidities on mycelial growth of *M. nitida* and *M. brachytricha*.

dry out more rapidly than the natural substratum because the sulphuric acid in the bottom of the Van Tieghem cells absorbs all excess humidity above a given percentage. The natural substrate might well have contact with damp earth and be kept moist by capillary water. Zeller (1920) points out that the saturation point of wood fiber is reached at 95.0 per cent relative humidity, below which point the spore germination of basidiomycetous wood-destroying species is low, for the fibers seem to demand water at their expense. Above this point, germination is as high as 75.0 per cent and higher. Probably a similar condition would exist in nature in the case of these species of *Magnusia*.

EFFECT OF HUMIDITY ON GROWTH AND REPRODUCTION.—To discover the effects of humidity on growth and reproduction, a series of experiments was carried out somewhat similar to the first series on the effect of humidity on conidial germination.

To obtain the desired relative humidity for Petri dish cultures, desiccators 9 inches in diameter and

7¼ inches high were used. Seventy-five mm. Petri dishes containing potato-rat dung agar were inoculated with square blocks of agar of uniform size containing the mycelium of *M. nitida* and *M. brachytricha*. Two plates of each species were made up for each humidity in each series. The plates were inverted, covers removed, and the cultures were placed on the perforated porcelain plate above the sulphuric acid solution. The covers of the desiccators were then sealed, and the whole apparatus was kept at room temperature (from 20°C. to 24°C.) in indirect light. The following relative humidities were used: 100, 91.2, 80.6, 70.4, 60.7, 49.0, and 29.5 per cent.

As was found in the experiment on the effect of humidity on conidial germination, the optimum relative humidity for growth was below 100 per cent; in the case of mycelial growth, it was at 91.2 per cent, at which point *M. nitida* grew an average of 37 mm. and *M. brachytricha* an average of 34 mm. in nineteen days (fig. 2). Below 91.2 per cent relative humidity there was a gradual decrease in the diameter of the colonies of both species, which was particularly noticeable at 60.7 per cent and below. At every relative humidity *M. nitida* grew more extensively than did *M. brachytricha*.

The amount of aerial mycelium (table 1) produced by each species varied with the humidity. At 100 per cent relative humidity the aerial mycelium of both species was long, fluffy, and loose in texture, but at 91.2 per cent the aerial mycelium of *M. nitida* was much shorter and more compact, whereas *M. brachytricha* produced none. At 80.6, 70.4, and 60.7 per cent there was a decrease in the amount produced by both species—a decrease noted chiefly in the length of the hyphae making up the aerial mycelium. At 49.0 per cent relative humidity and below, no aerial mycelium was produced by either species and, while growth occurred, it was obvious that this had taken place before an equilibrium between agar and atmosphere had been reached. It is doubtful if further growth after inoculation would have occurred had there been an immediate equilibrium between the substratum and the atmosphere. In general, *M. nitida* produced aerial mycelium more consistently and over a wider range of humidity than did *M. brachytricha*.

The production of conidia in both *M. nitida* and *M. brachytricha* (table 1) was excellent down to 60.7 per cent relative humidity, but at 91.2 per cent the conidiophores were more numerous than at either 100 or at 80.6 per cent or lower. In one series of experiments the conidia were consistently produced uniformly over the surface of the colonies of both species, and in the other series, conidia were just as consistently formed only in the center of the colonies of both species. Since in both series the same lot of medium was used, external factors were apparently responsible for this slight variation in conidium production.

The range of humidity for cleistothecium production in *M. brachytricha* was from 100 down to 49.0
